THE MADDON CRAFTSMEN, INC., CAMDEN, N. J.

## Preface

The first edition of this book appeared in 1923 as *Synthetic Resins and Their Plastics*. The overwhelming number of synthetic resins and synthetic plastic products germinating in the twelve years intervening, together with the recognition of a broader knowledge of the causes and nature of resinification, have led to a change in the title of the present volume to *The Chemistry of Synthetic Resins*.

This, however, does not signify that any condensation or elimination of sections on plastics and plastic molding has occurred in the preparation of the second edition. On the contrary, the treatment of material on the subject has brought about a considerable expansion in the number of pages devoted to plastic molding.

Thus while a complete revision of the text has been required to provide the present edition, both the scientific and technical aspects of synthetic resins have, it is hoped, been given about equal weight. At the same time effort has been made to provide a complete literature survey of all species of synthetic resins.

Data, information and assistance have been received from so many sources that an impartial acknowledgment of all of these founts of information and help is difficult. My thanks, therefore, are given whole-heartedly to those (especially the members of my personal staff and of the Ellis-Foster Company) who have rendered assistance in one way or another in the completion of this exacting task, an undertaking the extent of which by comparison with the first edition clearly indicates the enormous degree of activity the past years have brought in the realm of synthetic resins.

# THE CHEMISTRY OF SYNTHETIC RESINS

## Chapter I

### Introduction. Definitions. Classifications

On all sides the comment is heard that the present time constitutes the era of synthetic materials. The resources which nature provides now seem pitifully inadequate both in quantity and in quality to cope with the demands of industry and it is greatly to the credit of the scientist and more particularly to that of the chemist that the ever-increasing and varying demands of mankind can still be satisfied. The number of products which can be made from more elemental substances seems almost incredible. Naturally it is outside the scope of this book to consider them all but it is hoped that the present text provides a comprehensive survey of one important section—that of the chemistry of synthetic resins.

Progress in the synthetic resin industry can be said to have taken steps in two directions: (1) There has been a continuous development of new types of resins and (2) new applications have been made of the better-known materials. To adapt the more or less standard resinous products to new uses has necessitated, in some cases at least, modifications of various kinds.

The possible substitution of synthetic plastics for wood, metal and glass has received much consideration. The advantages of plastics have been repeatedly emphasized and are only too obvious. Cheap resins, as well as cheap methods of fabrication, are essential, however, before any extensive use can be made of molded or laminated products as structural materials. The manufacture of large molded cabinets and tanks and the employment of laminated board in table and desk tops and in wall paneling are dependent on the relative cost of these materials as compared with others now in use.

To produce a resin which promises any hope of commercial success, the chemist is limited to the use of relatively cheap raw materials—for example, phenol, urea, formaldehyde, glycerol, phthalic anhydride, acetylene, rubber and petroleum. For his laboratory preparation to remain other than a curiosity, it must have some properties superior to those of already existing products. In many cases the only apparatus required to make a synthetic resin is a test tube. This fact perhaps in part explains the cause of existence of several thousands of synthetic resins which have been reported and are discussed in the following pages. The huge number of recognized synthetic resins constitutes a figure which does not appear quite as disheartening, however, when it is realized that none of the known commercial synthetic resins is without a fault. There are usually one or more characteristics of a particular resin which preclude its application for some purpose to which other resins have been adapted. It is therefore evident that modifications of resins to improve their properties in one respect or another are necessary and must keep pace with the introduction of new types of resins of improved characteristics. Progress in the resin field, more so than in perhaps any other chemical industry, is largely conditioned by advances from the research laboratories.

Improvements in molding-technic have advanced the art of fabrication of plastics to such an extent that material costs of the molding composition are

now much more important than formerly. Among other things, perfection of automatic presses and mastery of the method of hobbing molds have reduced labor costs considerably. The introduction of injection molding methods is also in this direction. Cheaper molding compositions are therefore needed in order to keep pace with cost reduction on the mechanical side.<sup>1</sup>

Going back over the dozen years which have elapsed since the first edition of this book was published, one may enumerate the more important events in the field of synthetic resins as follows:

1. The expiration of certain patents on making and using phenol-formaldehyde condensation products has caused a greater diversification in the manufacture of these materials as well as a very substantial reduction in cost to the public.

2. A great concentration of effort has been applied to the development and production of certain resins of the phenol-formaldehyde type which would dissolve in drying oils to yield varnishes of an improved character. This effort has been productive of important results and having been contemporaneous with the rise of the nitrocellulose lacquer industry in the United States has, to a considerable extent, succeeded in putting a curb on the expansion of lacquers in the coating field. One great advantage arising in the use of lacquers was their quick-drying properties (since lacquers are generally made from nitrocellulose and resins dissolved in volatile solvents and the coating is dry as soon as the solvent has evaporated). Various forms of phenol-formaldehyde resins have, therefore, been brought forth which not only dissolve readily in drying oils but yield a varnish basis which when applied to a surface dries with comparative rapidity. This feat of increasing drying speed has given rise to numerous terms based on the rate of drying such as "2-hour" varnishes and "4-hour" varnishes. (See Chapter 19.)

3. The development and marvelous growth of alkyd resins, especially those containing a drying oil component, is another feature of the era. Alkyd resins are made by reaction between a polyhydric alcohol and a polybasic acid. For a great many years it has been known, as noted in the 1923 edition, "Synthetic Resins and Their Plastics," that a dibasic acid, typified by phthalic anhydride, and a polyhydric alcohol, illustrated by glycerol, would combine to form a resin, but it remained for the inauguration of the lacquer industry to stimulate research on the preparation of resins which would be compatible with nitrocellulose and produce durable lacquers. In the infancy of the lacquer industry the principal source of resin suitable for incorporation with nitrocellulose was dammar, the supply of which was limited and the quality variable because of the natural origin of the resin. The development of synthetic resins of the alkyd type supplied the lacquer industry with an adequate source of resinous material of uniform quality and such an abundance of compatible synthetic resin undoubtedly was in part instrumental in aiding the rapid expansion of this industry. A further development in the alkyd resin field is the type of resin in which a modifying agent is present to establish controlled resinification of the resin complex. The acids of drying oils were found adapted to the purpose. It is well recognized that drying oils lose much of their desirable siccative qualities if they are chemically changed or altered, yet the drying oil radical was found in the case of the alkyd resins still to be capable of drying. As a result these compositions, applied as coatings, yielded quick-drying finishes which were extremely durable even on outside exposure. Such compositions departed entirely from the usual lacquer formulation. Nitrocellulose was omitted. The drying oil alkyd resin was used alone dissolved in a cheap solvent instead of being mixed with nitrocellulose in a much more expensive solvent vehicle. Despite the profound alteration of the drying oil

<sup>1</sup> Carleton Ellis, *Ind. Eng. Chem.*, 1934, 26, 37.

glyceride molecule by resinification, the high rate of drying of this type of siccative resin was striking. (See Chapters 41-49.)

4. The introduction of chlorinated rubber under the trade name of Tornesit has provided the coating industry with another material for making paints or varnishes of unusual resistance to alkali and acids. (See Chapter 55.)

5. The recrudescence of vinyl resins also should be noted. These had been fairly well studied at the time the first edition of the book was published in 1923, but commercial development was lacking. In the intervening years, however, several large companies have undertaken the manufacture of vinyl resins and the output is becoming substantial. (See Chapters 51-52.)

6. The rapid rise of urea resin molding compositions is another characterizing feature of the past twelve years. Beginning, in the first instance, with unproductive efforts to make clear glass-like articles which would be permanent, the industry eventually developed in the molding field, since the absence of dark colors in the resin enabled attractive new shades of molded goods to be placed on the market. This development was stimulated by the fact that urea resins could be rendered thermosetting and could therefore compete with many of the phenol-formaldehyde products. The urea resins possess an advantage over the phenolic resins in that molded articles can be made which enjoy a degree of translucency greatly superior to that of the phenol-formaldehyde molded goods. The light-stable qualities of the urea resins, coupled with the ability to make the delicate pastel shades which hitherto had been denied the industry by phenolic resins, created an unprecedented demand for the products made from urea sources. (See Chapters 26-32.)

It is not intended from the foregoing to imply that the natural resins lack many useful properties. On the contrary, some of them, e.g., shellac, have been difficult to duplicate in the quality of hardness and toughness. (See Chapter 2.) Yet there is a limit to the supply of the best qualities of natural resin. In consequence they are subject to adulteration and to price fluctuation. The search for substances to replace the natural products was instigated many years ago with a view to having a guaranteed quality of material at hand, thereby overcoming these two serious drawbacks. Correlated problems naturally arose from these researches, soon to assume major significance. The discovery of a class of fusible resins which when heated above a certain critical temperature formed infusible as well as insoluble resins is one such instance. Some of these products, generally designated as thermosetting resins, are now, as is well known, the basis of the resin-filler molding powders.

An idea of the rapid growth of the synthetic resin industry is obtained by a study of Table 1 which has been compiled from various sources.<sup>2</sup>

In discussing the subject of synthetic resins it is of course necessary to define a resin. One cannot rely solely on the picture presented by the thought of the familiar natural resins since the common synthetic resins have very little resemblance to the natural resins. It is probable that for this reason the term "synthetic plastic" has often been used when speaking of synthetic resins. However, as is pointed out later, plastics include a much broader field.

A resin may be defined as a solid or semi-solid, complex, amorphous mixture of organic substances, having no definite melting point and showing no tendency to crystallize. A resin is characterized by such physical properties as a typical luster and a conchoidal fracture rather than by any definite chemical composition.<sup>3</sup>

<sup>2</sup> O. Wilson, *Ind. Eng. Chem.*, 1927, 19, 917; 1933, 25, 227. J. N. Taylor, Report of Chemical Division, U. S. Bureau of Foreign and Domestic Commerce, 1933. See also *Chem. Age* (London), 1929, 20, 523; 1931, 24, 418; 1932, 26, 52. *J.S.C.I.*, 1928, 47, 1270; 1930, 52, 662. *Literary Digest*, 1932, Jan. 2, 40.

<sup>3</sup> It is interesting to note the derivation of the word "resin." The word is probably derived

TABLE 1.—Production of Synthetic Resins in the United States.\*  
1920-1933

Year	Tons Produced	Year	Tons Produced
1920.....	2000	1927. . . . .	7,500
1921.....	800	1928 . . . . .	10,000
1922.....	3000	1929 . . . . .	16,500
1923.....	3500	1930.....	15,500
1924.....	5000	1931. . . . .	17,500
1925.....	6000	1932. . . . .	15,500
1926.....	6000	1933.....	22,500

\* The figures for 1920-1926 are for phenol resins only. Those for 1927-1931 are for resins of coal-tar origin only. About 60-65 per cent of the latter can be considered phenolic. The 1932 production is distributed as follows: Coal-tar origin, 14,500 tons; Non-coal-tar origin, 1000 tons. The production for 1933 was divided thus: Phenol, 12,500 tons; Phenol-resol, 3250 tons; Alkyd 5000; Urea or thiourea, 1600; All others, 150 tons. For purposes of comparison 6500 tons of pyroxylin plastics were produced in 1933.

The term "resin" was originally applied to the natural resins which occur in certain plant secretions.<sup>4</sup> The naturally occurring resins are for the most part light-colored vitreous substances, perfectly hard or at most only slightly sticky at ordinary temperatures, but capable of softening or melting when heated. They are insoluble in water but can be made to dissolve in certain organic solvents.<sup>5</sup>

A synthetic resin is merely, as the name implies, a resin formed by synthesis, using non-resinous organic materials as reactants. Synthetic resins do not necessarily possess the same properties as the natural resins. It is for this reason that the term "synthetic resin" is preferred to "artificial resin." An artificial resin would be one made to imitate a natural resin in its properties whereas a synthetic resin can possess properties which are entirely its own. The term "synthetic balsam" has come into use to designate the synthetic resins which are of the nature of viscous syrups, analogous to the naturally-occurring oleoresins and balsams. Thus the field of synthetic resins covers a group of organic materials ranging from viscous liquids to hard, infusible amorphous solids.

In the broadest sense the various bitumens, tars and pitches must be included as resins. It is of course difficult to define specifically the words "bitumen," "tar," "pitch," etc., since in common usage the terms are somewhat interchangeable. This is only natural because these substances are very similar in chemical and physical characteristics.

The international definition for *bitumen*<sup>6</sup> decided upon in 1928 states that it is a generic term for the "mixtures of natural and pyrogenous hydrocarbons and of their non-metallic derivatives, which may be either gaseous, liquid, viscous or solid, but must be completely soluble in carbon disulphide." In popular usage only the solid or viscous-liquid bitumens have been included in the definition. The solid or semi-solid bitumens containing only a small proportion of volatile constituents are now called *asphaltic bitumens*.<sup>7</sup> *Asphalt* is defined as a natural or mechanical mixture of solid or viscous bitumens with inert mineral matter.<sup>8</sup>

from the Latin word *rasis* and the Greek word *rhasis*. The Latin *rasis* means "a kind of rough powdered pitch used to mix with wine," thus denoting one of the early uses of natural resins. The Greek *rhasis* is a gradation variant of *rhetine*. The letter combinations *re* and *rhe* are from a word meaning "to flow." This can be seen in the prefix *rheo* and the word *stream*. "Universal Dictionary of the English Language," E. P. Dutton and Co., New York, 1932.

\* A notable exception is shellac, which is exuded by an insect rather than by a plant. See Chapter 2.

<sup>5</sup> Natural resins are often called "gums" or "gum resins" by the varnish maker. They are not true gums, however. The true gums are also excreted from plants but they are water-soluble, or at least form gels in water, and are insoluble in alcohol. Gum arabic and gum tragacanth are examples of true gums.

<sup>6</sup> W. J. A. Butterfield, *J.S.C.I.*, 1928, 47, 294T.

<sup>7</sup> An account of the various uses of solid and semi-solid bitumens is given by T. Temme, *Asphalt u. Teer*, 1934, 10, 167; *J. Inst. Pet. Tech.*, 1934, 20, 432A.

<sup>8</sup> F. J. Nellensteyn (*J. Inst. Petroleum Tech.*, 1924, 10, 320; 1928, 14, 134) concludes that asphalt contains elementary carbon in colloidal form as its essential constituent.

*Tars* are the viscous liquids obtained in the destructive distillation of organic substances (e.g., wood tar, coal tar). Their composition is of course dependent upon the initial materials and the temperature of distillation. *Pitch* is the black or dark brown, solid or semi-solid residue obtained by the partial evaporation or fractional distillation of a tar.<sup>9</sup>

Synthetic resins are often referred to as plastics, thus denoting that one of their uses is as molding material. Plastics of course include all substances capable of being worked and molded (e.g., clay, plaster, cement, putty, metals). Naturally such a broad field is not to be covered in this book. Such organic plastics as nitrocellulose, cellulose acetate and casein are likewise outside the scope of synthetic resins. It may be argued that these substances are resins according to the

Courtesy Bakelite Corp.

FIG. 1.—Compounding Polystyrene with Coloring Agents.

definition given, but at the same time they are not truly synthetic resins but are modified natural products.<sup>10</sup>

The term "plastic" is applied to anything which possesses plasticity; that is, anything which can be deformed under mechanical stress without losing its coherence and is able to keep the new form given it.<sup>11</sup> It is often stated that the term "plastics" as applied to the molded articles on the market is a misnomer since such rigid materials are anything but plastic. The term is applied in the industry to those materials (i.e., cellulose nitrate, cellulose acetate, casein, synthetic resins) which are in a plastic state during some part of their manufacture.<sup>12</sup> It is obvious that materials which are plastic at ordinary temperatures

<sup>9</sup> See D. M. Wilson, *J.S.C.I.*, 1924, 3, 924. H. Abraham, *Ind. Eng. Chem.*, 1913, 5, 11. J. Le Braz, *Glaces et verres*, 1934, 538, 4; *Chem. Abs.*, 1934, 28, 6991.

<sup>10</sup> Some exception is made to this ruling, however, and such materials as modified natural resins (Chapters 37-39) and modified rubber (Chapters 54-55) are discussed in this book.

<sup>11</sup> Plasticity is discussed more fully in Chapter 3.

<sup>12</sup> See J. Obrist, *Kolloid-Z.*, 1928, 45, 82; *Chem. Abs.*, 1928, 22, 4208. C. Stark, *Gummi-Ztg.*, 1931, 45, 1242; *Chem. Abs.*, 1931, 25, 3778. W. J. Jenkins, *J.S.C.I.*, 1933, 52, 241. H. C. Parker, *J.S.C.I.*, 1933, 52, May 19, 818.

will not form useful molded articles. Hence substances are used which are either thermoplastic or thermosetting.<sup>13</sup>

A thermoplastic substance is one which is adequately rigid at normal temperatures and under ordinary conditions of stress but is capable of deformation under heat and pressure. This property is permanent in a thermoplastic substance; that is, the process of deformation under these conditions can be repeated. In contrast to this is the term "thermosetting" or "thermohardening." A thermosetting substance is one which possesses initially the properties of a thermoplastic but which under the influence of heat undergoes chemical change so that it is no longer thermoplastic but is permanently infusible. In the case of synthetic resins there are two types of thermosetting materials. The quick-thermosetting resins (e.g., phenol-aldehyde and urea-aldehyde) undergo rapid chemical change to an infusible form during the molding process. The slow-thermosetting resins require considerable time for conversion to an infusible condition.

It is of course obvious that the quick-thermosetting type of resin is always sought for in molding operations since the process is speeded up considerably in this case. In molding a thermoplastic material it is necessary to cool the mold every time in order to avoid distorting the finished article, but in the use of a thermosetting material the molded piece can be removed without any preliminary cooling. The speed with which the molding can be done depends greatly on the time taken for the hardening operation.

#### CLASSIFICATION OF RESINS

The various methods of classification of synthetic resins fall into three groups: by physical characteristics, by chemical characteristics and by initial reacting materials. The last-named method is the one employed in the present work. A perusal of the table of contents shows that the general order of starting materials is as follows: hydrocarbons, phenols, aldehydes, ketones, amines, natural resin acids, polyhydric alcohols and polybasic acids, vinyl compounds, rubber, sulphur and fatty oils. This sort of classification is necessary because of the large number of resins reported and because most persons are familiar with resins from such standpoint.

In the classification adopted by Kienle<sup>14</sup> synthetic resins are grouped according to their behavior after the initial condensation. There are three main divisions:

1. **Heat-convertible resins.** Those which become infusible by the action of heat. Included in this group are the glycerol-polybasic acid resins, acetylene derivatives, polyolefin resins and the phenol-aldehyde resins.

2. **Heat-nonconvertible resins.** Those which remain thermoplastic. Examples are the glycol-polybasic acid resins, vinyl resins and certain of the phenol-aldehydes (acid type).

3. **Element-convertible resins.** Those which become infusible through the action of certain elements such as oxygen or sulphur. This group includes the glycerol-polybasic acid-drying oil resins<sup>15</sup> and olefin-sulphur resins.

Synthetic resins may also be classified as:

##### A. Monomeric

E.g., phenolphthalein, aroclors.

<sup>13</sup> The term "resin" is restricted by some to thermoplastic resins, and the word "resinoid" is used to designate the heat-hardening resins. See H. L. Bender, H. F. Wakefield and H. A. Hoffman, *Chem. Reviews*, 1934, 15, 123; *Chem. Abs.*, 1934, 28, 7042.

<sup>14</sup> R. H. Kienle, *Ind. Eng. Chem.*, 1930, 22, 590. See also Chapters 4 and 41.

<sup>15</sup> See Chapter 44.

**B. Polymeric****1. Linear macromolecules**

E.g., vinyl resins, polystyrene, polyindene, novolacks and heat-nonconvertible alkyds.

**2. Tridimensional macromolecules**

E.g., heat-convertible alkyds, phenol-aldehyde resins, urea-aldehyde resins and the drying oil alkyds.

Another method of classification is that used by Carothers.<sup>16</sup> Polymers are divided into two classes:

**1. Addition or A polymers.** In this class the molecular formula of the monomer is identical with that of the structural unit. Included here are polyolefins, polyoxymethylenes, polystyrene and unsaturated hydrocarbons.

**2. Condensation or C polymers.** In this type the molecular formula of the monomer differs from that of the structural unit. Examples are polybasic acid-polyhydric alcohol esters, phenol-aldehydes, urea-aldehydes, etc.

The importance of the field of synthetic resins is indicated by the large number of articles which have appeared on the subject. The appended list includes a great many of the general reviews already published.

## Chapter 2

### Need for Synthetic Resins and Types Desired

As was pointed out in Chapter 1, the principal motive in creating synthetic resins is not to imitate the natural products but to improve on them. As wonderful and useful as the natural resins are there is not one that is entirely perfect and all of them have faults which should be eliminated. Then too, the day must be faced when the supply of natural resins will be exhausted; and even before that, the time when the best specimens are gone and only inferior grades remain.<sup>1</sup>

In the development of many fields in which synthetic materials are to replace natural ones the first step is to imitate the natural product, but later the trend is toward the creation of substances never before encountered. Witness, for instance, the dye industry which has grown to enormous proportions. The first accomplishment was the actual synthesis of the naturally occurring product and later the imitation of natural colors. Finally with increasing discoveries entirely new dyes were produced which were far superior to anything to be found in nature. In the case of synthetic resins the same trend is not only possible but has actually taken place. The search is now for resins having properties not possessed by any material in existence. In spite of all the resinous products mentioned in this work, very few have many desirable properties and not one is perfect.

A large use for natural resins has been in protective and decorative coatings, i.e., varnishes and lacquers. Of course there have been numerous other uses including the forming of molded articles, adhesives and fabric-impregnating materials. In the case of shellac, more than half of the amount produced is employed in moldings, principally for phonograph records. As has just been stated, however, the natural resins have been used mainly in varnishes. There are two principal types of varnishes, oil varnishes and spirit varnishes. The latter type, the spirit varnish, is merely a solution of a resin in a volatile solvent. Drying in this case involves the evaporation of the solvent, leaving the resin as a film on the surface to which the varnish has been applied. In a drying-oil varnish the oil and the resin together give the desired film. The oil itself on drying would supply a tough elastic film which however lacks sufficient hardness and gloss. The resin, on the other hand, when used alone may lack toughness and elasticity, but it imparts to the varnish film the necessary hardness and gloss and frequently improves atmospheric resistance.

The fossil resins at first glance appear almost perfect for varnishes because of their hardness and high gloss, but the disadvantage arises from the fact that they are insoluble in drying oils, owing to their high degree of polymerization.

<sup>1</sup> According to A. J. Gibson (*J.S.C.I.*, 1933, 52, (May 19), 88) the annual world-production of natural resins is approximately 750,000 tons. This is distributed roughly as follows: Rosin, 600,000; Copal, 36,000; Shellac, 32,000; Dammar, 11,000; Kauri, 5000; Acroïdes, 1200.

Among the various books dealing with natural resins may be mentioned: R. S. Morrell, "Varnishes and Their Components," D. Van Nostrand, New York, 1923. H. Wolff, "Die natürlichen Harze," Wissenschaftliche Verlags-G.m.b.H., Stuttgart, 1928. H. Hadert, "Tropische Lackrohstoffe," O. Elsner Verlags-G.m.b.H., Berlin, 1932. T. H. Barry, "Natural Varnish Resins," E. Benn, London, 1932. A. Tschirch and E. Stock, "Die Harze," Gebrüder Borntraeger, Berlin, 1933.

The resins must first be subjected to a melting process, known to the trade as "running," in order to render them soluble in drying oils. The result of the running is a depolymerization and a partial decomposition into oily constituents, causing a small, though not serious, loss of hardness. The difficulties encountered in using oil varnishes are evident. The work of "running" the varnish resin, adding driers and thinners, maturing and filtering could all be eliminated if a resin could be found which needed merely to be dissolved in appropriate solvents and applied to surfaces to form durable films.\* Another difficulty found in the use of oil varnishes is the long time required for the drying of the film. This is of course eliminated in the spirit varnish or lacquer. In this case the characteristics of the film depend on the resin or cellulose compound used. Thus far, however, few substances have been found which possess luster and hardness and at the same time are tough and elastic.

Hence the work on new coating compositions is toward more rapidly drying varnishes which give tough lasting films. This work can be carried out along at least two different paths.

(1) Incorporate a drying element within the synthetic-resin molecule. This has already been tried with remarkable results in the drying oil-polyhydric alcohol-polybasic acid resins. (See Chapter 44.)

(2) Synthesize a resin soluble in a cheap solvent which on evaporation leaves a hard, tough enduring film.

It may well be said that as yet the coating industry has not found the perfect resin. For coating compositions the ideal resin must not only possess the sum total of all desirable physical properties demanded of a film-forming material, but must also present economic advantages in its production and in its use. The cost of the resin is not the entire consideration. More important is the cost of the final film; that is, solvents are of prime importance.

Accordingly, the present trend of the coating industry is towards the development of a resinous substance of suitable properties, the one requisite of which is that it must be soluble in cheap solvents. Moreover, the resin should not retain the solvent in a tenacious way. On the application of a coating solution, the solvent should evaporate freely, at least to the degree where the film becomes dry and hard.

Other properties wished for in the resin, or properties which should be obtained through admixture with other materials, are that it must be of proper color and it must give films of proper gloss and adhesion. The melting point must be high enough so that no softening occurs under ordinary rise of temperature. The flexibility must be such that no cracking takes place at low temperatures, the film remaining free from brittleness. The film must be hard enough to wear well and resist abrasion. It must be waterproof, heat-resistant, noninflammable, and light-stable. It should resist alkalies, acids and other reagents, and should satisfactorily combat corrosion. Change to an insoluble form shortly after application also is desirable. The film should undergo little or no progressive change on aging such as is encountered with ordinary drying oil paints where continued oxidation occurs with consequent volume changes and chalking. All these qualities may be comprised in the condition that the resin must produce films which are light-colored, tough and durable.

In addition to a search for the perfect resin more study must be made on the causes of defects produced in varnish films, sometimes through no fault of the resin itself but through the wrong method of application, the wrong choice

\* See Carleton Ellis, *Ind. Eng. Chem.*, 1933, 25, 125.

of solvents or mistakes in preparing the surface to be coated. Gardner<sup>3</sup> has classed the causes of opacity in films into 3 groups.

1. The action of actinic rays. This may lead either to a chemical decomposition or to physical changes resulting in a lowering of the elasticity or a decrease in hardness.

2. The production of heterogeneity in a film during drying through the precipitation of solid matter. This difficulty arises principally from differences in the rates of evaporation of solvents. When mixtures of solvents are used the more rapid evaporation of one solvent may cause the solid matter to precipitate

*Courtesy Modern Plastics*

FIG. 2.—Storage Tank for Phenolic Resin Used in High-gloss Varnishes.

in the remaining liquid. Also, the rapid evaporation of a solvent may cause cooling, resulting in the condensation of moisture on the film and a subsequent clouding effect.

3. Adsorption of liquids into the pores of a dry film. If the liquid adsorbed possesses nearly the same refractive index as the film a translucent film will be produced. If the refractive index varies widely from that of the film, opacity results. It should be noted however that the mere whitening of a film does not prove that the protective power has been lost.

A study on the tackiness of films from resin solutions has been made by Wolff.<sup>4</sup> It was concluded that tackiness is caused by the formation of colloidal

<sup>3</sup> W. H. Gardner, *Ind. Eng. Chem.*, 1931, 23, 1402.

<sup>4</sup> H. Wolff, *Farben-Ztg.*, 1920, 25, 668; 1922, 27, 2086; *Chem. Abs.*, 1920, 14, 2092; 1922, 16, 2610. H. Wolff and C. Dorn, *ibid.*, 1922, 28, 31; *Chem. Abs.*, 1923, 17, 216.

gels consisting of resin and residual solvent. To overcome this difficulty Wolff suggested either:

(1) The use of as large a proportion as possible of a single solvent in which the resin is very soluble;

(2) The incorporation of an additional solvent of suitable evaporation rate to slacken the fractional evaporation of solvents; or,

(3) The selection of such a combination of solvents that the least volatile is the best solvent.

Another problem in the study of solvents for varnishes and lacquers is to find those which will give the proper viscosity to the liquid being applied and at the same time will dissolve enough film-forming material so that only the minimum number of coatings will be necessary.<sup>6</sup> The cost of the solvents must be kept in mind, also, as was stressed previously. It might be mentioned that the odor and toxicity of solvents must be considered when the coating compositions are to be used on a small scale.<sup>6</sup> In large-scale operations, however, such properties are of minor importance if the solvents are cheap enough, since suitable means can be provided for eliminating dangerous or objectionable odors (e.g., conveniently placed vents for withdrawing the vapors).

The advent of cellulose lacquers and then the development of new synthetic resins (particularly the alkyd resins, Chapters 41-49) have been the cause of considerable rivalry in the coating field. As was mentioned before, the oil varnishes in most cases give desirable coatings but possess the disadvantages of slow drying and of poor weather-resistance. Consequently the perfection of low-viscosity nitrocellulose and cellulose acetate solutions was welcomed because it meant that quick-drying, moisture-resistant films were available. The lack of proper adhesion and flexibility in the early cellulose ester coatings as well as poor resistance to light hindered the full development of their use and paved the way for synthetic resins which would yield rapid-drying solutions and at the same time give films with the proper gloss, durability, adhesion and weather-resistance.<sup>7</sup> Advantages which have been pointed out<sup>8</sup> for the synthetic resin solutions include fast drying, excellent appearance, high hiding power, good adhesion, great resistance to light and to weather conditions and ease of application. The covering power, adhesion and resistance to light are qualities which make these finishes superior to the cellulosic lacquers.

Although one object in the manufacture of synthetic resins has been to replace or improve upon natural resins in coating compositions, another and undoubtedly greater development has been the making of plastic materials. The advantages of plastics have been emphasized repeatedly and are only too obvious. A plastic material has far greater adaptability than wood, metal or glass for the forming of articles of furniture, structural material and the like, provided that sufficient

strength can be imparted to it and, more important, that the material can be produced cheaply enough.

In order to form a perfect molding material a synthetic resin must meet a number of requirements. The most fundamental of these is that the resin can be easily molded or cast. Of course its melting point or softening point must be sufficiently high so that the molded article will keep its shape under the conditions in which it is used. A desirable quality in this connection is that the material will become infusible during the molding operation. This is exhibited notably in the urea-formaldehyde and phenol-formaldehyde resins.

Not only must the material mold easily but in the molding operation the resin should not stick in the mold since this involves loss of time and material.

*Courtesy Catalin Corp.*

FIG. 3.—Molding a Phenol-formaldehyde Resin. Molds Are Made of Lead.

The molded article should be capable of reproducing the high polish of the mold so that very little work is necessary on the finished article before it is ready for marketing. It should be noted here that if the resin has any chemical action on the metal of the mold, staining will result and as a consequence the finished article will be poorly made.

Not only should molded articles show a high polish but they should possess attractive colors. There is a great demand for light colors in synthetic resins because of the beauty which can thereby be imparted to molded articles. Hence the investigator in synthetic resins attempts to produce colorless or light-colored resins.\* This does not mean, however, that new dark-colored resins will be valueless, since they may possess other properties which outweigh the disadvantage of the dark color. For instance, if the resin is thermosetting, it can be used in moldings in which the primary requirement is strength and hardness, and color is of minor significance.

The electrical resistance and dielectric strength of synthetic resins is of im-

\* For a review on light-colored resins see C. W. Rivise, *Plastics*, 1929, 5, 189, 211, 254, 266, 317; *Chem. Abs.*, 1929, 23, 5600.

portance since the great development in the use of electrical apparatus and appliances of all kinds has created demands for an insulating material which can be formed into almost any shape conceivable and at the same time possess sufficient mechanical strength to make its use feasible.<sup>10</sup>

The chemical inertness of a synthetic resin has a great deal to do with its commercial success. It should at least not become stained or spotted by hot or cold water and should resist the action of mild acids and alkalies. In addition it should be immune to the action of some of the common organic solvents. It may seem paradoxical to expect a synthetic resin to dissolve in cheap organic solvents to form a varnish and at the same time expect a finished surface or a molded article of the resin to resist the action of these same solvents. What is meant is that the resin should be initially soluble in these solvents to form the varnish and at the same time should be capable of conversion into an insoluble form either by baking or by mere exposure to the oxygen of the air. Chemical inertness, fire-resistance and absence of odor help very much in promoting the use of synthetic resins in place of other materials.

Most important of all is the cost of a synthetic resin. Before any extensive replacement of wood or metal by molded or laminated products can be brought about, it is necessary to reduce production and fabrication costs to a minimum. This is of course accomplished by continued efforts to reduce the costs of raw materials and to improve the methods of resin manufacture and molding.

In discussing the properties desired in a synthetic resin it is well to present the characteristics of a few of the natural resins which have been found quite satisfactory, though not entirely perfect. Among the natural resins shellac possesses a good number of qualities desired in a synthetic resin. Shellac stands out from the other natural resins both in its origin and in its properties.<sup>11</sup> Whereas the other natural resins are strictly of vegetable origin, shellac occurs as a secretion from multitudes of lac insects feeding on certain types of hardwood or semi-hardwood trees. The resin is obtained principally from India, and in small quantities from Indo-China and Siam. For the most part shellac is cultivated; that is, the insects are placed on trees selected for the purpose. The insects suck sap from the host tree and exude resinous matter in which they become imbedded. Most of the resin is secreted by female insects since they outnumber the male of the species. The insects undergo two or three life-cycles a year, a new brood being produced during the process of resin-formation, and the parent insects dying in the secreted resin.

The shellac is harvested by breaking off the small branches incrustated with resin and then subjecting them to a crushing and winnowing operation to remove wood and bark. The material remaining, known as sticklac, consists of about 80 per cent resin contaminated with woody matter, wax and water-soluble constituents, principally a red dye, albumin and secreted sugars. The sticklac is broken into small pieces and washed to remove water-soluble material and woody particles. The cleaned resin, dried to about 2 per cent moisture, is known as seed-lac, in which form a great deal is exported.

In the process of making flaked shellac the material is subjected to what is essentially a filtering or straining operation to remove most of the dirt. The

<sup>10</sup> See H. Chase, *Plastics and Molded Products*, 1932, 8, 153. W. D. Owen and A. M. Thomas, *J. Oil, Col. Chem. Assoc.*, 1931, 14, 290; *Brit. Chem. Abs. B*, 1931, 1104. E. A. Bevan, E. N. Strathford and E. E. Walker, *Trans. Inst. Rubber Industry*, 1931, 6, 394; *Chem. Abs.*, 1931, 25, 4722; *J.S.C.I.*, 1931, 50, 134. With reference to insulating-varnishes see H. C. P. Weber, *Ind. Eng. Chem.*, 1925, 17, 11 and C. O. Harvey, *J.S.C.I.*, 1926, 45, 233.

<sup>11</sup> For general reviews on the preparation and uses of shellac see W. H. Gardner, *Ind. Eng. Chem.*, 1933, 25, 560. B. H. Knight, *The Chemist*, 1934, 11, 155. I. Mellan, *Chem. Industries*, 1934, 35, 315. A. F. Suter, *Brit. Plastics*, 1930, 2, 77.

seed-lac is placed in a long, narrow fabric bag and heated over an open-hearth charcoal fire. The ends of the bag are twisted so that the lac is extruded through the cloth<sup>12</sup> and drops onto a smooth hearth in irregular shapes which can later be worked into thin sheets, and, when cold, broken into flakes to form the ordinary shellac of commerce.<sup>13</sup> The principal uses for shellac have been in spirit varnishes, adhesives, fabric impregnation and moldings.<sup>14</sup>

For use in coatings, shellac has proved to be practically the best natural spirit-soluble resin. It forms films which are peculiarly tough and elastic and very resistant to abrasion. These properties can be demonstrated by attempting to grind a few flakes of orange shellac in a mortar. Not only is it difficult to reduce the flakes to a powder, but also the elasticity of the flakes causes them to fly out of the mortar. One disadvantage encountered with shellac films, however, is that they become stained and spotted by water and gradually lose their luster.<sup>15</sup> This has not been a serious drawback because the effect is not entirely permanent and because the hardness and toughness and quick-drying qualities of shellac varnishes far outweigh this slight fault.<sup>16</sup> The tough quality of shellac is a property to be sought for in synthetic resins intended for coatings.<sup>17</sup>

The thermoplastic character of shellac led to its extensive use in molding, principally in the production of insulating materials<sup>18</sup> and phonograph records.<sup>19</sup> The fact that it has a low coefficient of expansion enables shellac to be used for objects which must follow faithfully the intricate details of a mold. The low melting point of shellac is one drawback associated with its use, since moldings exposed to warm temperatures are apt to become distorted.

It is true that shellac polymerizes to an infusible product under the influence of heat<sup>20</sup> but the process is so slow that the heat-setting of the resin is not prac-

<sup>12</sup> The residue remaining in the cloth bag is known as "Kiri." The resin contained in this by-product has been used in cheap moldings. See S. Ranganathan and R. W. Aldis, *Brit. Plastics*, 1934, 6, 148.

<sup>13</sup> The estimated yearly production of shellac is 32,000 tons. A. J. Gibson, *J. S. C. I.*, 1933, 52, (May 19), 88. Of this the United States consumes 40, Great Britain 25 and all other countries 35 per cent. The distribution of uses is said to be: Phonograph records, 40 per cent, Varnishes and Electrical Insulation, 40 per cent; Hat- and Fabric-Stuffing, 10 per cent, Sealing Wax, Pyrotechnics, etc., 10 per cent.

<sup>14</sup> The chemical composition of shellac is considered in Chapter 50. For a method of determining insoluble matter, wax and ash in shellac see O. M. Olsen, *Ind. Eng. Chem., Anal. Ed.*, 1932, 4, 47. See also W. H. Gardner, *Chem. Met. Eng.*, 1933, 40, 144. The solubility of shellac in various organic solvents is discussed by W. H. Gardner and W. F. Whitmore, *Ind. Eng. Chem.*, 1929, 21, 226. W. H. Gardner and H. J. Harris, *Ind. Eng. Chem., Anal. Ed.*, 1934, 6, 400. See also M. Rangaswami and M. Venugopalan, *Indian Lac. Res. Bull.*, 1928, 1; 1929, 2; *Chem. Abs.*, 1929, 23, 5050; 1930, 24, 3660. Compatibility of shellac varnishes with nitrocellulose has been studied by W. H. Gardner and B. Gross, *Ind. Eng. Chem.*, 1935, 27, 168.

<sup>15</sup> See M. Venugopalan and M. Rangaswami, *Ind. Eng. Chem.*, 1930, 22, 911. W. H. Gardner, *ibid.*, 1931, 23, 1402. According to J. W. Paisley (*ibid.*, 1932, 24, 163), the addition of up to 10 per cent of tricresyl phosphate to shellac increases the moisture-resistance. See, however, Hutter, *Farbe u. Lack*, 1932, 547, 556; *Chem. Abs.*, 1933, 27, 624. M. Rangaswami and R. W. Aldis, *Indian Lac. Res. Inst. Res. Note*, 1933, 9; *Chem. Abs.*, 1934, 28, 2202.

<sup>16</sup> It has been found that increased water-resistance, hardness and flexibility are imparted to shellac films by a baking operation in which the temperature rises from 60° to 140°C in 1.5-2 hours. These properties are likewise improved by the addition of sulphur or sulphur chloride to the shellac varnish. See M. Rangaswami and R. W. Aldis, *Indian Lac. Res. Inst. Res. Note*, 1933, 4; *Brit. Chem. Abs.*, B, 1933, 316. M. Venugopalan, *ibid.*, 1933, 10, 12; *Brit. Chem. Abs.*, B, 1934, 370. R. W. Aldis, *ibid.*, 1934, 18; *Chem. Abs.*, 1935, 29, 946. Water-resistance is improved also by incorporating 2-3 per cent of urea or thiourea. M. Venugopalan, S. Ranganathan and R. W. Aldis, *Synth. and Applied Finishes*, 1934, 5, 161.

<sup>17</sup> The possibility of applying shellac coatings by electrodeposition from alkali carbonate solutions is discussed by N. Narasimhamurthy and M. Sreenivasaya, *Ind. Eng. Chem.*, 1934, 26, 882.

<sup>18</sup> See W. H. Nuttall, *J.S.C.I.*, 1928, 47, 1367.

<sup>19</sup> For a general discussion on materials and methods in the manufacture of phonograph records see H. C. Bryson, *Brit. Plastics*, 1931, 3, 104, 160, 223, 259; 1932, 4, 48, 206; *J.S.C.I.*, 1933, 52, 495. See also R. Jones, *Brit. Plastics*, 1932, 3, 857.

<sup>20</sup> See, for instance, Swiss P. 95,239, 1923, to Mantle Lamp Co. of America; *Kunstst.*, 1923, 13, 31. See also A. F. Suter, *Brit. Plastics*, 1930, 2, 77 and W. Nagel and E. Baumann, *Wiss. Veröffentlich. Siemens Konzern*, 1932, 11, 99; *Chem. Abs.*, 1933, 27, 856; *Brit. Plastics*, 1932, 4, 250. Considerable study has been made on rendering polymerized shellac soluble. See R. W. Aldis, *Indian Lac. Res. Inst. Res. Note*, 1933, 7, 11; *Chem. Abs.*, 1933, 27, 3092; *Brit. Chem. Abs.*, B, 1934, 370. M. Venugopalan and R. W. Aldis, *ibid.*, 1934, 17; *Chem. Abs.*, 1935, 29, 946. M. Rangaswami and R. W. Aldis, *Indian Lac. Res. Inst. Bull.*, 1934, 19; *Chem. Abs.*, 1936, 29, 946.

ticable in good molding technic.<sup>21</sup> Therefore, in making molded articles from shellac and fillers the mixture is treated as a thermoplastic rather than a thermosetting material.<sup>22</sup> It is quite evident why the search is continually being made for plastic materials which will harden very rapidly when subjected to the pressures and temperatures used in molding.<sup>23</sup>

In addition to shellac, another natural product exhibits many desirable properties which should be possessed by synthetic resins. This is the material known as Japanese lac, which occurs as the sap in the Oriental tree, *Rhus verniciifera*.<sup>24</sup> The coating produced by this material is noteworthy for its hardness, luster and durability. In the opinion of Morgan<sup>25</sup> the type of resin towards which investi-

gators should strive is a product of this nature which preferably could be applied in the liquid condition at ordinary temperature without the use of a volatile solvent.<sup>26</sup>

Another method of approach in the development of new resins is to modify natural resins so that they will be more adequately suited for the uses intended for

<sup>21</sup> S. Ranganathan and R. W. Aldis (*Indian Lac. Res. Inst., Res. Note*, 1933, 14; *Brit. Chem. Abs.*, B, 1933, 719) state that conversion of shellac to a tough mass requires 8 minutes at 220°C. and 127 minutes at 120°C., increase in pressure delaying the reaction. Urea, hexamethylenetetramine and mineral and polycarboxylic acids (e.g., hydrochloric, oxalic) accelerate the change. By preheating shellac at 110°C. before molding, the heat-stability of finished specimens is said to be improved. S. Ranganathan and R. W. Aldis, *ibid.*, 1933, 13; *Chem. Abs.*, 1934, 28, 3918.

<sup>22</sup> Methods of molding shellac are described in Chapter 68.

<sup>23</sup> Ordinary shellac contains 75-80 per cent of ether-insoluble resin, termed "pure lac resin." It is stated that this resin has a quicker rate of thermohardening and greater water-resistance than ordinary shellac. L. C. Verman and R. Bhattacharya, *Tech. Paper, London Shellac Res. Bur.*, 1934, 1. L. C. Verman, *J.S.C.I.*, 1935, 54, 86T.

<sup>24</sup> See K. Miyama, *J. Coll. Eng. Imp. University, Tokyo*, 1908, 4, 89, 201; *J.S.C.I.*, 1908, 27, 456; 1909, 28, 318. H. Pudor, *Z. offentl. Chem.*, 1910, 16, 315, *J.S.C.I.*, 1910, 29, 1119. Anon., *Bull. Imp. Inst.*, 1910, 8, 22; *J.S.C.I.*, 1910, 29, 639.

<sup>25</sup> H. H. Morgan, *Appl. Chem. Reports, Soc. Chem. Ind.*, 1921, 6, 346.

<sup>26</sup> For investigations on the constitution of Japanese lacquer see R. Majima and S. Cho, *Ber.*, 1907, 40, 4390. R. Majima and J. Tahara, *Ber.*, 1915, 48, 1606. R. Majima and G. Takayama, *Ber.*, 1920, 53, 1907. R. Majima, *Ber.*, 1909, 42, 1418; 1922, 55, 172, 191; *J. Tokyo Chem. Soc.*, 1919, 40, 91; *Chem. Abs.*, 1919, 13, 2862.

them. Thus has come about the production of ester gum and chlorinated rubber.<sup>27</sup> These can be considered "semi-synthetic resins" since they do not exactly fit into the class of synthetic resins nor are they truly natural materials since their properties have been modified.

Because of its acid nature, and consequent lack of resistance to moisture, rosin was once a greatly despised member of the natural-resin group. Reduction of of the acidity through esterification with glycerol to form ester gum helped a good deal in promoting the use of rosin in varnishes. A greater move was the discovery that excellent varnishes are formed from rosin and tung oil. Although the fossil resins were not entirely compatible with tung oil, rosin was found to have exceptional merit in this respect. In addition rosin prevents the gelatinization of tung oil at the temperatures used in preparing varnish. At the same time the tung oil gives sufficient waterproofness to the varnish, so that the two raw materials are mutually beneficial.<sup>28</sup> Ester gum is likewise compatible with tung oil, giving even better results. Consequently the modification of a once-despised natural resin has placed it in the ranks of the most useful resins.

The chapters which follow present a great number of attempts to produce synthetic materials to meet the demand for new and better coatings and improved molded articles. It should be borne in mind that relatively few of these have been really successful and that as a consequence the search still continues both for resins with improved qualities and for new uses for those resins already developed. As the public becomes more and more "synthetic-resin conscious" the number of resins and the diversity of their uses increase.

<sup>27</sup> Modified rosin and other resins are treated in Chapters 37-39. Chlorinated rubber is discussed in Chapter 55.

<sup>28</sup> R. L. Houck, *Paint, Oil, Chem. Rev.*, 1928, 86, (21), 10; *Chem. Abs.*, 1929, 21, 5336, has suggested there may be a reaction between the acid resin and the tung oil to form mixed esters so that the varnish film in this case may be regarded as a synthetic resin.

## Chapter 3

### The Resinous State

The nature of solids and liquids is perplexing and complicated save in idealized cases. Between the solid and the liquid there are a number of transitions which are of a puzzling character. A great number of names has been used to distinguish these intermediary states. They have been called gels, glasses and also vitreous, plastic, colloidal, mesomorphic and amorphous states. By considering matter as being divided into two classes,<sup>1</sup> it is possible to avoid some of the ambiguity. In the crystalline state, matter is arranged in a definite order according to the laws of lattice structure. In the amorphous state, matter is in complete disorder.

When a solid material is dissolved in a volatile solvent and the solvent allowed to evaporate, three very distinct phenomena may take place: (1) the solvent on evaporating deposits crystals; (2) the solid may precipitate as an amorphous mass; or (3) no solid separates but the solution becomes more viscous, yielding the solid as a vitreous or glassy mass. In the first instance there is such a directing force between the molecules that at the point of crystallization the molecules become arranged in a lattice structure and solidification takes place rapidly. In the formation of amorphous materials, however, the attraction forces do not necessarily disappear but no one force predominates and no regular lattice can be formed.

The formation of a glassy mass can be observed not only when a solid is dissolved in a liquid but also in the case of a pure substance. If a pure molten compound is cooled below its melting point, the melt begins to crystallize at one or at several points. At a certain temperature, i.e., a few degrees below the melting point, it is almost impossible to prevent the tendency to crystallization. If one quickly passes through this range of temperature, the tendency toward crystallization vanishes and the melt becomes viscous and solidifies to a glass.\*

Normally the glassy state is associated with transparent silicate glass, but an obvious extension is to such a material as vitreous arsenious oxide. The general physical characteristics of a glass are, however, shown by many brittle synthetic resins, and indeed lines of demarcation are exceedingly ill-defined.

The case of dextrose can serve as an illustration of a typical non-siliceous glass. Crystalline dextrose, when heated at 160°C. for 10-15 minutes and cooled to the ordinary temperature at a pressure of 4 atmospheres in nitrogen, forms a clear colorless material, which softens at 40° and forms a thick viscous liquid at 60°. The refractive index-temperature curve shows a change in slope over the interval 20-30°, i.e., at below the softening point.\* Other glassy materials of a similar nature (e.g., from glycerol-glucose, propylene glycol-glycerol-glucose) have been prepared.\* Reference may be made in this connection to the remarkable adhesive properties of overheated glycollic acid. By heating glycollic acid

<sup>1</sup> This classification is due to M. Polanyi, *Umschau*, 1930, 34, 1001; *Chem. Abs.*, 1931, 25, 1132.

\* For application of this phenomena to mineral oils to account for variation of melting points accompanying the change of state, see P. Woog, E. Ganster and F. Coulon, *Compt. rend.*, 1931, 193, 850; *Chem. Abs.*, 1932, 26, 1424.

<sup>2</sup> G. S. Parks, H. M. Huffman and R. F. Cattoir, *J. Phy. Chem.*, 1928, 32, 1366.

<sup>3</sup> G. S. Parks, S. B. Thomas and W. A. Bilkey, *J. Phy. Chem.*, 1930, 34, 2028; *Chem. Abs.*, 1930, 24, 5210.

gradually to 150°C. and maintaining the temperature at this point for several hours and cooling a hard compact product is formed with excellent properties as an adhesive. This material may well be a glass.<sup>5</sup> Fused sucrose octa-acetate is found also to have a glassy or resinous character, and its use as an ingredient of anhydrous adhesives, as a gum substitute of lacquers and as a plasticizer has been suggested.<sup>6</sup>

Berger<sup>7</sup> considers the formation of a glass from the liquid state as continuous process, taking place through the viscous (supercooled) state to the brittle state. Accordingly a break occurs in the property-temperature curve at the transition from the supercooled to the vitreous state. Brittle glass is, according to this conception, not merely a supercooled liquid, but represents a definite state of matter. According to a theory of the vitreous state developed by Rosenham<sup>8</sup> glass is considered as an assemblage of atoms in which certain molecular groupings may occur. Even in irregular assemblages of atoms, there are tendencies toward some aggregation even though most of the linkage bonds are unsatisfied. A small portion of the interatomic linkages is operative and the latent heat of fusion (representing the energy stored in unsaturated bonds) is largely retained in cooling and setting. This accounts for the low absorption of heat during melting and the little or unnoticeable evolution of heat on cooling which is a characteristic property of glasses. There is an intermediate stage between the elastic solid and the viscous liquid in which the rupture of bonds may occur for a time after the application of stress but with a storage of sufficient energy to arrest any further rupture. Morey,<sup>9</sup> on the other hand, on the basis of x-ray patterns considers that the distinguishing feature of the glassy state is a random, non-repeating atomic network.

Zachariasen<sup>10</sup> maintains that the atoms in glass are linked together by forces which are essentially that kind which exist in crystals. The mechanical properties of glass are directly comparable to those of crystals, in fact, the strength of glass may excel that of the corresponding crystalline form. In glass, however, the atoms oscillate around definite equilibrium positions over large ranges of temperature and even though one may consider a three-dimensional network in glasses as in crystals, the network is not periodical and symmetrical. The arrangement can not be entirely one of randomness, however, inasmuch as the internuclear distances do not sink below a given minimum value. The principal difference between the network in a crystal and that of glass is the symmetry and periodicity in the first instance and the absence of these properties in the latter. Each unit cell in a crystal must contain an integral number of stoichiometric molecules because all the unit cells are alike. In glass, however, the unit cell is infinitely larger. As in crystals the transparency of glasses can be explained on the basis of an extended network.

Very few of the known oxides readily produce a glass. Whereas silicon dioxide and boron trioxide form glasses, attempts with titanium oxide and aluminum oxide have not been so successful. Goldschmidt<sup>11</sup> has tried to correlate the ability to form glass with the value of the radius ratio  $R_a/R_0$  for the oxides  $A_mO_n$ . The radius ratio of the oxides which have been prepared in the vitreous form is about

0.2-0.4. This arrangement corresponds to the tetrahedral arrangement of oxygen atoms around the atom *A*. Zachariassen derives a formula for the gross chemical composition of a glass to be  $A_mB_nO$  where *B* represents the cations, *A* represents other cations, *m* and *n* give the number of cations *A* and *B* per oxygen atom. It is concluded that a glass will have the most advantageous properties if *n* has a value of about 0.5. Cations *A* must carry a small charge and have a large radius. Hagg,<sup>12</sup> however, believes that large and irregular groups exist in melts. In the inorganic glasses the formation of these groups is due to the possibility of coördinating oxygen atoms in a definite way. If the number of available oxygen atoms is less than necessary for the formation of polyhedral groups with the required coördination, the polyhedra are linked together sharing oxygen atoms. The resulting groups delay crystallization and thus cause the formation of glass.<sup>11</sup>

Tammann,<sup>14</sup> to whom much of our knowledge of glasses and supercooled liquids is due, has described an experiment which illustrates a similarity between a resin and a glass. The height of rebound of a steel ball from a rosin surface at temperatures between 20-70°C was measured. An almost constant rebound was observed between 20-50°, and then there was a sharp decrease to no rebound at 70°. Somewhere in this temperature range rosin lost its brittleness, just as a glass does, though it showed no sign of softening.<sup>15</sup> In this respect rosin behaved as a typical glass. The hardness of the surface of glass, as measured by the pressure needed to cause initial rupture of the surface, diminishes continuously over the softening range, but this diminution commences before softening sets in. The hardness vanishes at the lowest temperature at which threads can be drawn from the glass.<sup>16</sup>

The kinetics of the transformation of the supercooled melt to the crystalline phase has been studied especially by Tammann.<sup>17</sup> In a supercooled liquid, the molecules do not tend rapidly to assume their positions in the space lattice of the crystal because crystallization would set in immediately below the melting point. Only a small portion of the molecules are properly oriented and these serve as nuclei or crystallization centers from which further crystallization takes place. In supercooled melts, those molecules possessing a low enough kinetic energy will stick together to form a minute crystal which acts as a nucleus. At lower temperatures, however, the production of nuclei becomes less favorable because of the decrease in molecular motion and the increase in viscosity. Both of these factors are unfavorable for the formation of nuclei.

There is considerable experimental evidence to indicate that one of the factors influencing crystallization is the treatment of the liquid previous to cooling. Othmer<sup>18</sup> observed a diminution in the tendency to crystallize with increased preheating of the liquid. No simple explanation can be offered to explain this behavior. Certain solutions can not be made to crystallize except by inoculating. Supersaturated solutions of sugar and tartaric acid remain stable.<sup>19</sup> On careful filtration through glass wool, supercooled melts of salol, thymol, benzophenone,

o- and m-cresol, acetophenone and guaiacol have no tendency toward spontaneous crystallization.<sup>20</sup>

Although crystallization centers can not exist in a melt at temperatures above the melting point,<sup>21</sup> Richards<sup>22</sup> has suggested that the crystal form may persist above the melting point provided an adsorbent is present for which the heat of binding of the crystalline adsorbate is greater than the liquid adsorbate.

Haber<sup>23</sup> differentiated two distinct processes in the formation of the nuclei: one, the rate of aggregation and second, the rate of arrangement. The rate of aggregation corresponds to the coagulation velocity whereas the rate of arrangement is related to the formation of nuclei and of crystallization proper. The disparity between the rate of aggregation and that of arrangement determines whether the particle precipitates as crystalline or amorphous. When the rate of aggregation is large and that of arrangement is small, the particle will appear as amorphous, which may become crystalline after a long time. On the other hand, when the rate of arrangement is also large, no amorphous mass will be formed.

Von Weimarn<sup>24</sup> has developed an elaborate theory to account for crystallization and the supercooled state. Crystals may be divided into three classes: first are those crystals in which not any one of the three dimensions shows a marked development over the other two. These are termed "neutral" crystals. In the second class are those crystals in which one dimension is less developed than the other two. The third class takes in those crystals with one dimension highly developed; an example of this last class is to be found in the fibrous crystals.

In solution there exists around each crystal a vectorial field or vectorial atmosphere which prevents the crystals from approaching one another and which allows parallel orientation. Due to differences in concentration there will be diffusion currents but these again will be vectorial. Crystallization can therefore be looked upon as a "vectorial polymerization."

From a very extensive investigation on the form of precipitates, von Weimarn sums up his results in the following equations:

$$N = K \frac{P}{L}$$

where

$N$  is the number of crystallization centers,

$K$  is a factor involving viscosity,

$P$  is the degree of supersaturation and

$L$  is the solubility.

If  $K$  and  $P$  are small and  $L$  relatively large then the value for  $N$  will be small. The resulting precipitate will be in the form of a small number of large crystals. If  $K$  and  $P$  are large and  $L$  small, then  $N$  will be large and the precipitate will be in the form of a large number of very small crystals. Under these conditions the whole mass sets to a gel. In other words, when the solutions are very dilute, the solid separates as a crystalline form. At low concentration, the velocity with which nuclei are formed is very small and the crystals grow slowly in this weakly supersaturated solution. In concentrated solutions, however, jellies are formed inasmuch as at high concentration the rate of the formation of nuclei is very great and these nuclei form a felt-work without crystallization.<sup>25</sup> Low solubility and high molecular weight are properties

<sup>25</sup> P. P. von Weimarn has shown that one can obtain any anhydrous salt in a gelatinous form by precipitating under conditions where the supersaturation is enormous. By mixing concentrated solutions of manganous sulphate and barium sulphocyanate a gelatinous precipitate of barium sulphate comes

which are associated with gels. Conditions which bring about supersaturation, such as rapid cooling or slow mixing, also favor gelation.

In crystals of ultramicroscopic size, the vectorial fields will be liquid and the whole aggregate will appear either liquid or semi-liquid. At no time, however, does crystallinity cease to exist and crystals can be macro-, micro- or ultramicro-crystalline. The amorphous state arises more through the limits of microscopic resolution than through any differences in structure.

Moreover when crystals become sufficiently disaggregated mechanically, materials are obtained which, though solid, can not be distinguished from liquids. A supercooled melt, therefore, is considered to be identical with that produced mechanically.

### PLASTICITY

Plasticity as well as viscosity both imply the meaning to flow but it is generally conceded that soft solids do not behave in the same manner as viscous liquids. Because of the overlapping of solids and liquids, differences in interpretation arise and no one definition can satisfactorily account for all of the conflicting phenomena. One of the most satisfactory definitions is as follows: plasticity is the susceptibility to and the retention of deformation.<sup>26</sup> In contrast, a brittle body under mechanical stress loses its coherence. An elastic body, on the other hand, though easily deformed, readily assumes its original shape.

Several factors are involved, however, in the susceptibility to deformation. Both wax and sealing wax are brittle if the pressure is applied rapidly; they can be considered plastic if the rate of deformation is slow. Glass under the same conditions can be considered as plastic at ordinary temperatures. Under high temperatures, it behaves as a deformable liquid which retains its shape by rapid cooling. Spring<sup>27</sup> reported that under sufficiently high pressures, solids behaved like mobile liquids; this apparent fluidity only occurs when there is a shearing force together with pressure.<sup>28</sup>

Part of the anomaly in plasticity can be avoided by the use of the classification of Polanyi,<sup>29</sup> namely, that there are two forms of matter, crystalline and amorphous. In the ordered state are included metals and salts whereas in the amorphous state are such substances as glass, varnishes and the like. These substances differ markedly with respect to plasticity. When amorphous materials change their form, the molecules change places. Increasing the temperature causes an increase in the mobility of the molecules. The plasticity of amorphous substances, therefore, is greatly dependent on temperature. In crystalline substances, the plasticity even at high temperature (that is, below the melting point) changes but very little due to the fact that the molecules are bound and can not change places.<sup>30</sup>

Metals, however, do have a plasticity; this can be shown in the case of polycrystalline metals which can be forced through an orifice under pressure.<sup>31</sup> The plasticity depends upon the movements of the molecules over one another.<sup>32</sup>

Athermal plasticity arises in unicrystals (zinc and cadmium). They possess

down temporarily. Concentrated solutions of calcium chloride and ammonium carbonate yield gelatinous calcium carbonate. See "Grundzüge der Dispersoid Chemie," 1914.

a low elongation limit which at low temperatures becomes independent of loading velocity and temperature. It appears, therefore, that at absolute zero, deformation would occur under conditions not markedly different from that of room temperature.<sup>33</sup> In the thermally plastic substances (glass, pitch and shellac) where plasticity depends on heat motion, one would expect that at absolute zero the plasticity would disappear.<sup>34</sup>

Another type of plasticity occurs in which two phases enter, one the solid and the other liquid. Apart from such factors as fineness, softness, laminated structure and roughness of surface, one must consider the viscous layer between the particles and the surface reaction between the liquid and the solid phases.<sup>35</sup> This type of plasticity has been termed "colloidal" because the most important factor appears to be the development of an active surface.<sup>36</sup> Substances which are wetted by a suitable liquid (which will not dissolve the particle) will form plastic masses provided the material is sufficiently divided. Silica, tungstic oxide and red phosphorus will give good plastics with water alone. Other oxides (titanium, zirconium and thorium) gave no plasticity with water; with a strong acid solution in place of the water the plasticity improved markedly. A sufficiently great thickness of the liquid layer is important for obtaining strong plasticity.<sup>37</sup>

There is another phenomenon closely related to both the particle size and to loose packing and this is known as "thixotropy." A material is considered thixotropic which when at rest becomes solid but which liquefies again on agitation. This process of solidification and liquefaction can be repeated as often as desired. The phenomenon requires a sufficient thickness of liquid layers between the particles and also demands some sort of attractive forces between the solid particles. These same forces influence the consistency of plastic masses. Freundlich and Juliusberger<sup>38</sup> emphasize that plasticity and thixotropy exist when packing is not too close, where there is a large volume of sedimentation and where no Osborne Reynolds phenomenon enters.<sup>39</sup>

The importance of the particle shape in plastic masses was pointed out by Le Chatelier.<sup>40</sup> When the particles are of a decidedly non-spherical shape, they display characteristic streaks on stirring showing a persistent layering effect. Concentrated suspensions of quartz powder stirred in water reveal streaks of silky luster.<sup>41</sup>

Wiener<sup>42</sup> as a result of theoretical investigations showed that any substance which was intrinsically lamellar in structure would in sufficiently small layers

<sup>37</sup> Close packing is detrimental to plasticity. When moist fine powders are stirred they appear to become dry and hard; on standing they become moist again. This is known as the Osborne Reynolds's effect (*Phil. Mag.*, 1885, (5) 20, 469) and is due to close packing. When dislocated, the particles separate and the amount of water is not sufficient to fill the interstices. The mass under these conditions appears dry. During the settling the particles become closely packed again with enough water to fill the cavities and the particles appear moist. The Osborne Reynolds's effect is the exact opposite of thixotropy.

show the phenomenon of double refraction, the "rod double-refraction." A case of this type was early found in fibrous alumina.<sup>43</sup> Ambronn<sup>44</sup> investigated the simultaneous double refraction by rods and the specific double refraction. Rods of celloidin (nitrocellulose) and cellulose, when examined, showed that the celloidin had a negative sign whereas cellulose was positive. This appeared to Ambronn to be a confirmation of Nägeli's<sup>45</sup> theory of crystalline micellae.<sup>46</sup>

Particle size as well as shape likewise has a definite bearing. To form plastic masses there seems to be a distinct optimum in size which varies from 0.3-3 $\mu$ .<sup>47</sup> When the particle is too small, even the influence of the non-spherical shape, so necessary for cohesion, falls off rapidly. The smaller particles, moreover, have a stronger Brownian movement and this movement tends to make the mass less firm.

The particle size cannot be too large. The maximum diameter appears to be in the neighborhood of 10 $\mu$ .<sup>48</sup> Particles when too large become more closely packed thereby decreasing the amount of liquid between the layers, as well as decreasing the area of the interfacial surface. Both of these factors are detrimental to elasticity.

The effect of mechanical treatment, and especially that of the fineness of dispersion, on plastic properties is of prime importance in the case of certain synthetic resins, just as it is in the case of clays and similar systems. Manfred and Obrist<sup>49</sup> have discussed this phase of the problem for plastics made from casein. Casein itself is not inherently plastic.<sup>50</sup> When pulverized or finely ground casein is mixed with 15-45 parts of water, an immediate swelling of the casein particles sets in. The subsequent plastification is carried out either entirely by mechanical means, or by a combination of mechanical and chemical treatment. In the first case extrusion machines are used, resembling those employed in the rubber industry. The casein particles are gradually compressed; under these conditions their mutual interference and friction causes considerable disaggregation. When this change has proceeded to its full extent, the particles pass into a zone heated to 80-85°C., where they become welded together, forming a more or less homogeneous product.

On this basis, the process of forming a plastic material consists first of all in a disintegration of pre-existing aggregates. The re-aggregation to form a plastic substance occurs between rod-like particles, which set into chains. If the disaggregation is carried to a stage at which the rod-like particles themselves are broken down, the chain structures do not form so readily. The elastic properties of artificial and natural plastics, therefore, depend more on their condition of orientation, which is determined by the plasticizing treatment they receive prior to hardening or setting, than upon the initial chemical condensation.<sup>51</sup> This theory has been called the "principle of conformation by assemblage."<sup>52</sup>

Against such an extreme view there is much to be said. One very important fact which must not be overlooked is that resins, either natural or synthetic, are not composed of a single entity, but usually of several types of molecules. It may, indeed, be necessary for this condition to be fulfilled if a resin is to form.

In addition to this, specific chemical effects do undoubtedly enter into resin formation, though in a number of well-known instances it is the long rod-like molecules which form resins.

**Measurement of Plasticity.** Bingham<sup>22</sup> defined plasticity in terms of two independent factors. Under a small shearing stress, the solid would permanently hold its shape. Under a larger shearing stress, the solid could readily be deformed, worked or molded. In the case of a viscous fluid, a linear relation exists between the volume of flow and the rate of shearing stress. Plastic solids behave differently in that a definite amount of the shearing force is used up in overcoming the internal friction of the material. When the rate of stress is just equal to the yield value, that is, the point at which the plastic solid responds to the shearing stress, then the material is said to have reached its elastic limit. Increase in the stress beyond the elastic limit results in plastic flow.

Karrer<sup>24</sup> has suggested the following quantitative definition of plasticity:

a substance has unit plasticity which deforms a definite amount under some standard conditions when a force of 1 kg. per sq. cm. acts on it for 1 second, and the whole of this deformation is permanently retained. The name "pla" was suggested for the unit which could be measured in a plastometer. A sample of the substance to be measured is cut in the form of a small cylinder 1 cm. long and 1 cm. in diameter and is placed between two jaws of the same diameter as the sample; the upper jaw being movable in a vertical direction. A spring is then released, which causes the upper jaw to move down, imparting to the sample a deformation which depends upon its softness.

The amount of deformation is recorded on a dial. The pressure is released after a definite time (e.g., 1 second), and the amount of recovery in, say, 5 seconds, is also recorded automatically. The plasticity is then defined by

$$P = C \frac{D}{F}$$

where  $C$  is a constant,  $D$  is the deformation retained (expressed as a percentage of the initial length) and  $F$  is the deforming force.  $F$ , therefore, is a function of the hardness of the material, whereas  $D$  is governed by the permanent set.

Karrer has also developed expressions for the retentivity of the material and for its softness, some typical relative values can be seen in Table 2.

TABLE 2.—*Plasticity of Certain Materials.\**

Material	Temp.	Softness	Retentivity	Plasticity
Chewing gum				
Unmasticated . . . . .	20° C.	0.342	0.722	243
Masticated 15 times . . . . .	20°	0.284	0.843	2410
Masticated 30 times . . . . .	20°	0.256	0.814	2070
Beeswax . . . . .	20°	0.0545	0.25	13.6

Cast steel . . . . .	20°	0.000121	0.0278	0.00034
Crude rubber . . . . .	30°	1.16	0.0748	8.73
Smoked sheet . . . . .	100°	1.66	0.0345	50.7
Unmasticated . . . . .	140°	2.02	0.0692	139.9

\* E. Karrer, *Ind. Eng. Chem.*, 1929, 21, 770.

These figures give a general idea of the differences which arise in materials, all of which have some claim to be considered as plastic. Definition of temperature will also be necessary in defining plasticity, since for a great number of synthetic resins there is a large temperature coefficient.

Williamson<sup>25</sup> has pointed out that many dispersions do not exhibit a real yield

<sup>22</sup> E. C. Bingham, "Fluidity and Plasticity," McGraw-Hill, N. Y., 1922, 216 ff. See also J. Alexander, "Colloid Chemistry," I, 720.

<sup>24</sup> E. Karrer, *Ind. Eng. Chem.*, 1929, 21, 770; *ibid. Anal. Ed.*, 1929, 1, 158; 1930, 2, 96.

value and cannot be molded, yet their flowing properties resemble in some respects those of ideal plastics. Such dispersions are called pseudo-plastics. de Waele<sup>55</sup> gives as examples of this type of system cellulose nitrate sols, gelling gelatin sols and some liquid-liquid emulsions. True plastic systems resemble those which are pseudo-plastic, at a rate of shear which is above a certain critical value. The rigidity component manifests itself at low values of shear, but disappears progressively as the rate of shear is increased. The difference between the two states, then, appears to depend fundamentally on the lower rigidity of the pseudo-plastic state.

Bingham and Green<sup>57</sup> have shown that paints do not flow in accordance with the law of viscous flow but show certain properties of plastic flow. This failure of yield value and mobility constants in the equation of flow, Williamson, Patterson and Hunt<sup>58</sup> took as a measure of the brushing and flowing properties of paints. The method was based upon the manner in which the apparent fluidity varies with shear at low rates of shear in a modified Stormer<sup>59</sup> viscosimeter. McMillen,<sup>60</sup> however, showed that this instrument does not allow accurate measurement of apparent fluidity in leveling, due to friction. The method was, in effect, one of extrapolation.

A paint or an enamel is plastic in the sense that a certain amount of force is necessary to change its shape. The necessary force is termed yield value. One substance which lowers the yield value and at the same time increases the dispersion of pigments is bodied linseed oil. McMillen<sup>60</sup> points out that paint at a shearing stress below its yield value must be considered a gel; above the yield value, it must likewise be considered a sol. Upon the removal of the higher shearing stress, the sol reverts to the gel condition. In this sense, therefore, paints exhibit thixotropic phenomena.

Oil paints, which are essentially suspensions of pigments in a non-volatile liquid medium, must not remain fluid too long while being brushed else they will flow due to the action of gravity and all leveling power would be lost. Reasonably quick solidification is necessary apart from the other physical and chemical effects of drying. This initial solidification is due to thixotropy. If the solidification is too rapid, brush marks will remain due to the fact that surface tension forces have been arrested.

An oil color varnish represents a very complex colloidal system in which a large number of colloids are simultaneously present. It ordinarily consists of oils, resins, thinners, driers and pigments, each of which can be considered colloidal. The changes which take place on drying either by oxidation or polymerization likewise give rise to colloidal material. Moreover, in such a system the colloids may be of the irreversible and of the reversible types. The latter may in a sense function as a protective colloid. In the making of a varnish, the resins must be first heated in order to break down the complex molecule into more simple components in order that they can be dispersed. If the resins are insufficiently heated before they are dispersed, some of the particles may be thrown out of solution. Oils are then added together with driers and thinners. On aging, certain components are precipitated leaving the varnish which is thus rendered less viscous but of easier working properties. Upon loss of the solvent, a

resin-like layer is obtained, a layer which behaves like a gel in one sense and not unlike glass in another.<sup>61</sup>

Wolff<sup>62</sup> has discussed the colloidal chemistry problems of varnish making. When lead resinate is dissolved in linseed oil at 150°C. to increase the rate of drying, a precipitate may form slowly or not at all owing to the mucilaginous material in the oil. The presence of a protective colloid was deduced by Schlick<sup>63</sup> who found that Prussian blue settled rapidly when ground with benzene. When the color was ground in with a small amount of linseed oil and then diluted with benzene, a clear blue solution was obtained which passed unchanged through filter paper. On filtering through a collodion ultrafilter, a colorless solution resulted.

Microscopic observations on drying color varnish films invariably show the development of a distinctly cellular structure, usually within 2-10 minutes after application of the varnish. Bartell and Van Loo<sup>64</sup> consider such development to be a vortex-ring action produced and maintained by volatilization of the solvent which causes a localized decline in temperature and change in density of the film. The action ceases when most of the volatile constituents have escaped and the rigidity of the remaining film has increased. The ideal varnish, they believe, should possess enough fluidity after loss of the volatile thinner to permit sufficient flow to eliminate all evidence of the cellular structure and to effect even distribution of the pigment. Various defects observed in color varnish films are explained by them<sup>65</sup> on the basis of this vortex-ring action. Pitting arises from high interfacial tensions between the varnish and the applied surface, from the repulsion of the varnish from nuclei (precipitated from the oil body) with the same electrical charge, and from the vortex action which may leave the centers of the cells as open pores in the films. Seeding is due to the accumulation of the pigment on immiscible solids suspended in the oil, to insufficient wetting of the pigment by the oil body, and to vortex action which piles up the denser or larger particles at the centers or corners of the cells. Silting results from the regular alignment of cells in the varnish film coupled with the same vortex action which causes seeding. Surface dulling is caused by the interference of light from the uneven-celled surface of the film, the accumulation of the pigment or other immiscible phase at the air interface, and the addition of water to the mixed varnishes.

#### COLLOIDAL PHENOMENA

It has been noted that in an amorphous substance a gradual transformation occurs between the solid and the liquid states. At a certain temperature, therefore, the forces between certain molecules will have been overcome whereas other molecules will still cohere to the solid mass. The result is a mixture of "liquid" and "solid" particles and may be considered an "isocolloid," in other words there are freely moving molecules present near fixed ones. Moreover, if under the influence of heat molecules of a liquid can combine chemically with one another (either by polymerization or condensation) with the formation of larger molecules, complexes will eventually be formed where thermal agitation ceases. When-

ever there are freely moving molecules (i.e., liquid) co-existent with fixed molecules (i.e., solid), an isocolloid is again formed.<sup>66</sup>

Resins, as a rule, are not composed of single entities but consist of macromolecules of varying size. Resins can thus be considered as gels of highly polymerized organic substances where the disperse phase consists of a more highly polymerized form of the material composing the continuous phase.<sup>67</sup>

Another classification which has been made of these high-molecular-weight organic compounds is to call them "xerogels." These are gels which have been formed by drying. They are poor in liquid but are nevertheless coherent.<sup>68</sup> The term has also been applied to such natural colloids as cotton, wool, silk, hair, horn and to such artifacts as gelatin, leather, charcoal and cellulose derivatives (esters, ethers and the like) and to completely synthetic products such as phenol-formaldehyde resins and silica gel.<sup>69</sup>

The question as to just how many phases exist in gels is one which has been debated for a long time. Procter<sup>70</sup> postulated a one-phase theory on the basis of his results on the system, water-acid-gelatin in which equilibrium resulted from the combination of the gelatin and acid to form easily dissociable salts. The one-phase theory has also found support in Sutherland's<sup>71</sup> concept of chain molecules and in McBain's<sup>72</sup> view that identical colloidal particles are present in the sol and gel state.

Hardy<sup>73</sup> on the basis of microscopical study of gelatin concluded that the solid phase of gelatin consisted of a solid solution of gelatin in water. Gelation was essentially the separation of the sol into a solid open framework with an interstitial fluid phase. Ostwald<sup>74</sup> injected the concept of the two-phase liquid-liquid theory and this has been accepted by Bancroft.<sup>75</sup>

The third possibility remains that gels have a solid crystalline phase. This theory was originally proposed as early as 1835 by Frankenheim<sup>76</sup> and revived in 1858 by von Nägeli.<sup>77</sup> Gels were considered to be composed of molecular complexes, or micellae, with crystalline properties; the water being held by attraction in the interstices within and between the micellae. Butschli<sup>78</sup> introduced the idea that there were definite pores in the jelly and van Bemmelen<sup>79</sup> extended his concept to one where this cell-like structure was one of definite form hanging together forming a network. The more concentrated solution acted as a network of cell walls enclosing a more dilute solution of the same substance.

This concept of the crystalline structure existing in gels was studied by Scherrer<sup>80</sup> by means of x-rays. In certain of the rigid gels (silicic and stannic acids) there were well-marked interference patterns along with evidence of the amorphous state. The gelatin gel, however, yielded no evidence of crystallinity. These gels possess other characteristic dissimilarities. Silicic acid gel, on drying,

<sup>67</sup> There are, however, certain resins which consist of particles which are essentially of the same size. If all of the molecules were of the same size, then one would be dealing with liquids. Inasmuch as it is necessary to assume that in these liquids the particles are of colloidal dimensions, such liquid resins must be considered sols. Cf. R. Houwink, *loc. cit.*

develops pores which contain air and these pores can be filled by imbibition.<sup>22</sup> Elastic gels (gelatin) do not develop such pores and the dried gels will not imbibe foreign liquids. The work of Katz and Gerngross,<sup>23</sup> however, suggests that there is a molecular orientation. In the x-ray diffraction spectrum obtained from dry gelatin films, a diffuse ring and a wide sharp ring occurring in the unstretched material changed on elongation. The sharp ring dissolved into two crescent shaped parts.

Von Weimarn<sup>24</sup> considers as a gel any liquid which assumes throughout its mass a half solid, elastic consistency, keeping at the same time in a more or less degree its former transparency. Jellies may be classified as follows: (1) according to the method of formation. This class includes network jellies (gelatin) which gelatinize uniformly throughout the mass and also membranous jellies which gelatinize only on definite interfaces between two liquids in the act of mixing. (2) They may be classed according to the degree of dispersity of the primary particles. In network jellies this includes macro-, micro-, ultramicro- and sub-ultramicrocrystalline jellies; in membranous jellies, ultramicro- and subultramicrocrystalline jellies. (3) Jellies may be considered with respect to their consistency as being resin-like pastes, soft-elastic or solid jellies (glasses) or (4) according to the concentration of the disperse part; or (5) according to whether they are temperature-reversible or temperature-irreversible. In the formation of membranous gels, it is necessary to have a high specific supersaturation and low solubility of the precipitating substance. The less the solubility, the longer the gel remains. Membranous gels, on shaking thoroughly, sometimes pass over into the network gel. In the formation of network gels, the solubility must be low, the specific supersaturation high and in addition there must be abundant solvation.

Thomas and Sibi<sup>25</sup> have found that when aqueous solutions of such compounds as sorbitol acetate, benzoyl cystine, benzoyl tyrosine, quinine sulphate, opto-quinine sulphate and the like, are cooled they form transparent gels which initially appear homogeneous under the microscope. On standing, or on the addition of organic solvents (alcohol or acetone), the gels are transformed into masses of crystals in the form of flexible, intertwining hairs. When stirred or shaken, the structure is destroyed. The separation of the dispersion medium offers an explanation for the general phenomenon of syneresis. The crystals separating from the dispersion medium may be filtered, dried, re-dissolved and cooled to again form a gel. These experiments favor the view that gels contain a solid phase.

All of the gels so far considered have been those which are dispersed in water. Whitby<sup>26</sup> has called attention to the fact that hydrophilic colloids are always treated with respect to water. Organophilic colloids bring in a new problem inasmuch as various organic liquids may be used. There should, however, be a relation between the swelling of substances and the structure of the liquids in which the immersion takes place. In the case of the swelling of rubber in solvents, it was found that compounds with an active group (nitrile, aldehyde or ketone) were more effective as the length of the hydrocarbon chain increased.

Mardles,<sup>27</sup> in a study of the solvents for cellulose esters, determined that hydrocarbons, ethers and the like exert little or no solvent action whereas such

compounds as acetic acid, methyl formate or acetate, benzaldehyde, acetone, epichlorhydrin and ethyl tartrate are excellent solvents. Whitby<sup>87</sup> further points out that the solvents for cellulose esters are in general non-solvents for rubber.

In additional studies, it was found that polyvinyl acetate swells and disperses in organic liquids of high dielectric constant whereas polyacrylic acid is soluble in water and formamide but insoluble in acetone and alcohol. By treating the polymerized methyl acrylate with magnesium methyl iodide in anisole at 100°C., an impure tertiary alcohol is obtained.<sup>88</sup> This alcohol is soluble in alcohols and in benzene. The corresponding hydrocarbon is soluble in benzene and precipitated by ethanol.<sup>89</sup>

In further work with cellulose acetate, Mardles<sup>90</sup> traced the gelation in benzyl alcohol through three distinct stages: 1) the coalescence of fine particles into larger ones; 2) the aggregation of the large particles into clusters; and 3) the linkage of the clusters to a rigid gel structure. The reaction was measured by the equation

$$\eta - \eta_0 = \alpha e^{\kappa t}$$

$\eta$  is the apparent viscosity of the gelating sol

$\eta_0$  is the original viscosity of the sol,  $\alpha$ , depending on  $\eta_0$  and

$\kappa$  is the rate of gelation

The temperature at which  $\kappa$  becomes nil was taken as the maximum gelation temperature. Beyond this point the sol was relatively stable with time; below this point, part or whole of the dispersed particles aggregated to form a gel structure.

Wornum<sup>91</sup> has discussed the phenomenon of gelation on the basis of primary and secondary valence of the resin particle. The large molecules do not exist in the free state except in dilute solution. In more concentrated solutions, they exist as micelles. The molecules cannot be bound together except by the van der Waal forces and any micelle formed will be of an evanescent character. When secondary flocculates do form, the action is reversible (see Table 3—*a*, *b*, *c*). When the micelle (*d*) is built up by primary valence forces, it is not possible to disperse the mass without the rupture of bonds. Under conditions where no chemical interaction takes place (*e*, *f*), the forces are cohesive and the mass may be redispersed by using a proper solvent. When primary valence is involved, structures of varying degrees of complexity are built up (*g*, *h*, *i*) and can be redispersed only when cohesive forces are used to build up the particle (*h*).

<sup>90</sup> E. W. J. Mardles, *Trans. Faraday Soc.*, 1923, 18, 327.

<sup>91</sup> W. E. Wornum, *J. Oil, Colour Chem. Assoc.*, 1933, 16, 231.

Wornum has extended this concept to the formation of films. Where the oxidation of tung oil is rapid, the flocculates are small in size and the oil sets to a clear film. The webbing of tung oil is considered to be due to the random coagulation of the large flocculates. When partial orientation has a chance to take place, there is local coagulation resulting in the formation of small irreversible gel particles. This leads to a crystalline or "frosty" appearance. In the heat-bodying of tung oil at temperatures below 270°C., the acid in the  $\beta$ -position of glyceride has not sufficient energy to allow primary cross-valency to take place. It is only when the temperature reaches approximately 270° that cross-linkages occur with any ease and under the conditions flocculate growth occurs. Higher temperatures (310°) cause a very much greater increase in the number of cross-linkages which can take place with the result that a large number of small flocculates form. In under-cooked tung oil, the  $\beta$ -position has not been used. This favors the formation of large flocculates and hence "webbing." "Blooming" of the film is ascribed by Wornum to be due to the swelling of the large particles by water. Linseed oil has little tendency to produce large flocculates and consequently there is no tendency toward webbing. Varnishes can thus be divided into two types depending on whether the disperse phase consists of a large number of small flocculates or a small number of large flocculates.

Other factors also enter. The concept of a monomolecular film on a surface has become familiar from the work of Langmuir,<sup>82</sup> Adam<sup>83</sup> and others, and it is a well-established observation that in such a film the molecules may be oriented (e.g., in the case of substances with chain-like molecules, they may all be on end or tilted). Tammann<sup>84</sup> has concluded that the power of orientation in a film is restricted to those molecules which are able, under the conditions of the experiment, to undergo crystallization.<sup>85</sup>

High-molecular-weight organic substances behave differently from the fatty acids when spread on surfaces. Measurements were made on the thickness of the thinnest coherent films obtained by the evaporation of dilute solutions of macropolymers upon a mercury surface. The results are given in Table 4.

TABLE 4.—Films of Polymers <sup>a</sup>

Substance	Solution	Comparative Viscosity	Film Thickness
Rubber..	Ether		1.5 Å
Gelatin.	Water		7.0
Cellulose diacetate	Acetone		4.1
			3.8
			4.2
Cellulose triacetate	Chloroform	1960.0	9.85
Cellulose nitrate	Acetone	3025.0	2.50
		776.0	3.60
		13.5	4.23
		2.1	4.50
		0.2	5.00

molecules are exceedingly thin.<sup>66</sup> It has been concluded that the values found represent the transverse dimensions of the long chain-like or the sheet forms of the molecules which are orientated parallel to the surface rather than end-on as in the fatty acids. Inasmuch as in the high-molecular-weight compounds the chains are repetitions of certain units, there will be a potential alternating polarity along the chain, each periodic element containing both a polar and a non-polar grouping. This condition becomes accentuated as parallel orientation of the chain occurs. Where this takes place, the alternating polarity levels up the chains so that the sub-chains can form a space lattice.

The dimensions of the rubber film approximate the methyl group in rubber

which is about 1.5 Å. In the case of cellulose nitrate there appears to be a relation between the viscosity and the thinness of the limit film. Where the chains are short, the tendency will be toward vertical piling and overlapping. This also occurs in the case of proteins.<sup>67</sup>

## Chapter 4

### Nature of Resin Formation. Polymerization and Condensation. Fiber Structures. X-Ray Methods.

In order to prepare resinous compounds it is necessary to start with substances of rather low molecular weight. The transformation of various low-molecular-weight compounds into complex derivatives is usually termed "polymerization,"<sup>1</sup> but in this polymerization, two very distinct types of reactions can be distinguished: one which, for lack of a better term, is called polymerization and the other condensation. In a polymerization reaction the reactants are marked by a large degree of unsaturation and the resulting more saturated polymer is a multiple of the initial reactant, in other words the percentage composition remains unaltered. In condensation reactions, on the other hand, the final product is no longer a multiple of the monomer and in order to obtain the formula of the final condensate it is necessary to subtract the sum of the simple compounds which have been liberated during the condensation. Polymerization has been defined in various ways. Staudinger<sup>2</sup> considered polymerization as the union of like molecules to form a product of the same composition. Carothers<sup>3</sup> defined polymerization as the chemical combination of a number of similar units to form a single molecule; this definition embraced not only the condensation reaction but the true polymerization phenomena.

Other types of polymerization occur however, for example the "heteropolymerization" with which the name Wagner-Jauregg is associated and also copolymerization. Moreover, little distinction is made in the use of the term between the polymerization which involves comparatively few molecules and the polymerization wherein a great number of molecules enter into the formation of a single complex. Polymerization is used to designate the transformation of acetaldehyde to paraldehyde and the formation of polystyrene from styrene.

The term polymerization in this chapter will be used in the sense of macropolymerization and a distinction will be made between condensation and polymerization. The following types will be considered (1) addition or homopolymerization together with co-polymerization and heteropolymerization and (2) multicondensation. Among the polymerization polymers can be included such compounds as olefins, polyolefins and unsaturated compounds whereas multicondensation takes into account such reactions as polyesters, phenol-aldehydes and the like.

#### CLASSIFICATION OF POLYMERIZATION AND CONDENSATION

*Additive or homopolymerization* is a species of polymerization in which the

<sup>1</sup> R. H. Kienle and A. G. Hovey (*J.A.C.S.*, 1929, 51, 509) believe that the study of resin formation will develop new ideas concerning stereochemistry and bring about a better correlation between organic chemistry, colloidal phenomena and statistical mechanics.

<sup>2</sup> H. Staudinger, *Ber.*, 1920, 53, 1073.

<sup>3</sup> W. H. Carothers, *J.A.C.S.*, 1929, 51, 2546.

polymer is built up by the additive combination of the monomer. The process may be shown schematically as:

where "n" represents the number of monomeric groups of A, the monomeric unit. Since all of the groupings are alike, this is termed homopolymerization. For example, styrene ( $C_6H_5CH=CH_2$ ) on heating forms a resin of composition  $(C_8H_8)_n$  which may be represented:

*Co-polymerization* is the term applied when two or more substances polymerize at the same time to yield a product which is not necessarily a mixture of polymers; its properties differ from that of either polymer alone. The reaction may be considered to take place

or

*Heteropolymerization* is a special case of additive co-polymerization which involves the combination of a polymerizable, i.e., unsaturated substance and another unsaturated substance which by itself does not readily polymerize. Though maleic anhydride does not ordinarily polymerize, it will combine with stilbene in boiling xylene to yield a white amorphous heteropolymer in which the combining ratio is 1:1.<sup>4</sup> The structure has been represented as:

Condensation reactions take a variety of forms in the same manner as the addition polymerization types. A discussion of this type of reaction will be considered subsequently together with those reactions where additive polymerization and condensation occur together.

#### CHEMICAL STRUCTURE AND POLYMERIZATION

Both the physical and chemical concepts of the molecule have been used to account for ready ease of additive polymerization. One school considers that the resinous state is governed entirely by physical conditions; another that it is wholly due to definite chemical groups. Still another that it is a matter of chemical structure of the entire molecule.

Scheiber<sup>5</sup> emphasizes the purely physical aspects of resinification and considers

<sup>4</sup> T. Wagner-Jauregg, *Ber.*, 1930, 63, 3213.

<sup>5</sup> J. Scheiber, *Farbe u. Lack*, 1929, 86, 102; *Chem. Abs.*, 1929, 23, 2583; *Chem. Umschau*, 1928, 35, 181; *Chem. Abs.*, 1929, 23, 1867. See also *Farbe u. Lack*, 1927, 67; *Brit. Chem. Abs. A*, 1928, 1100. *Chem. Ztg.*, 1929, 53, 643; *Chem. Abs.*, 1929, 23, 5599.

the resinous state to be due to the formation of solid solutions (undercooled fusions) or to the formation of colloidal aggregates through condensation or polymerization. In these solid solutions and colloidal complexes, the orientation velocity lags behind the velocity with which irregular molecular complexes form.<sup>6</sup> Fonrobert<sup>7</sup> likewise characterizes the resinous state as a mixture of similar high-molecular-weight compounds. That high-molecular-weight substances have a profound effect on the velocity of crystallization from solution can not be questioned in the light of the experiments of Marc.<sup>8</sup>

Other factors, nevertheless, are in evidence. If the molecule contains groups which tend to destroy its symmetry, this fact will in itself favor resin formation. Vorländer<sup>9</sup> has noticed that para-substitution in the benzene nucleus tends to give rise to the liquid crystal or mesomorphic state of matter; the formation of liquid crystals he considers a manifestation of molecular regularity. The predominantly one-dimensional state is one of the most important factors for the formation and cohesion of anisotropic crystals inasmuch as the linear molecule has the greatest stability with the closest parallel packing.<sup>10</sup> The formation of supercooled liquids, on the other hand, is favored by those influences which prevent the formation of liquid crystals.<sup>11</sup> These influences include branched chains, an uneven number of side chain groupings and meta- and ortho-substitution; in other words, factors which bring about a dissymmetry in the molecule and tend to make it more difficult for a substance to solidify into the crystalline form. Under all conditions s-triphenylbenzene solidifies from the amorphous molten condition to a solid crystalline mass without marked undercooling. If the hydrocarbon is brominated, nitrated or aminated, the substituted products, in consequence of the dissymmetry of the molecule, form on rapid cooling transparent colorless amorphous lacs which remain in this condition at 15-20°C. On warming, the lacs become crystalline solids.<sup>12</sup> Triphenylmethane derivatives ( $C_6H_5$ )<sub>3</sub>C-X are dissymmetrical and such substances remain permanently in a supercooled amorphous state.<sup>13</sup> This view on the cause of resinification is also supported by data on such compounds as 1-nitrophenyl-3,5-diphenylbenzene (I), 1-p-aminophenyl-3,5-diphenylbenzene (II) or 1-acetyl-p-aminophenyl-3,5-diphenylbenzene (III).

These substances yield amorphous resins on supercooling.<sup>14</sup>

<sup>11</sup> D. Vorländer, *Z. physik. Chem.*, 1923, 105, 211; *Chem. Abs.*, 1924, 18, 1072.

<sup>12</sup> D. Vorländer, E. Fischer and H. Wille, *Ber.*, 1929, 62, 2836; *Brit. Chem. Abs. A*, 1930, 79.

<sup>13</sup> D. Vorländer, *Ber.*, 1925, 58, 1893; *Chem. Abs.*, 1926, 20, 584.

<sup>14</sup> D. Vorländer, *Z. angew. Chem.*, 1930, 43, 13; *Chem. Abs.*, 1930, 24, 4944.

By the ramification and bifurcation of the side chains, the molecule may become large enough in size to remain stationary. Vorländer<sup>15</sup> has shown that by increasing the size of the linear molecule, which decreases the tendency toward crystallization, it is possible to form liquid-crystal resins and lacquers. A substance of this type is as follows:

The formation of varnishes by polymerization and oxidation appears to be due to a decrease in the symmetry of the molecule which permits permanent supercooling or hardening of the amorphous mass. Something of this nature exists in drying oils. The ideal molecular structure to impart film-forming properties according to Scheifele<sup>16</sup> should consist of a central nucleus bearing three radiating thread-like groups. This structure is approached by linolenodihmolein and by cellulose esters.

Boekenooen<sup>17</sup> has drawn attention to the unsymmetrical arrangement of carbons

which can be found in many natural resins, gums and rubber. It appears as if nature had a special preference for this grouping in building up highly polymerized compounds.<sup>18</sup>

The presence of certain unsaturated groups, however, seems to be necessary for the occurrence of a reaction in an addition polymerization. The particular methods of effecting the reaction and the complex which can be formed depend on other factors than unsaturation alone.

Herzog<sup>19</sup> coined a term, "resinophore," for groups responsible for resinous properties. This term was first used with the carbodiimide grouping and was later extended to conjugated linkages.<sup>20</sup> Eibner<sup>21</sup> proposed to restrict the use of the term resinophore for the structural group present in the actual resin and introduced the word "resinogen" for the potential group. The presence of a resinogen in a molecule does not mean that a molecule is a resin but that under suitable conditions it may form one. Wolff,<sup>22</sup> on the other hand, considers resinogens as groups which tend to form compounds of high molecular weight but believes resins to be the result of conditions rather than of certain chemical groups.<sup>23</sup>

<sup>22</sup> H. Wolff, *Z. angew. Chem.*, 1927, 40, 1010; *Chem. Abs.*, 1928, 22, 3055.

<sup>23</sup> R. Oda (*Nia Kémio*, 1932, 5, 47; *Chem. Abs.*, 1932, 26, 2711) has developed a theory that in unsaturated compounds polymerization can occur only where there is a permanent dipole moment. Unsaturated compounds first arrange themselves to have a minimum electrical moment and then the union of chemical bonds takes place.

Autocatalysis has been considered by I. L. Kondakov (*Chem. Listy*, 1930, 24, 271, 293; *Chem. Abs.*, 1930, 24, 4933) to be a special variety of catalysis produced by the action of molecules of the same substance without the interaction of foreign substances. Autocatalyzable substances are characterized by unsaturated bonds or possess an unstable ring.

Broadly speaking any unsaturated grouping

acts as a polymerizing factor. The capacity for resinification is determined, however, not only by the grouping itself but also on external factors, among which can be mentioned heat, light, pressure and catalysts.

If all of the unsaturation is on a single atom,

the tendency for polymerization is greater. Conjugation of the groupings is even more effective

Additional conjugation further increases the tendency toward polymerization

Compounds like styrene which contain a negative group attached to the vinyl radical tend to form polymers in which the degree of polymerization is very high. Other negative groups include:

Group	Compound	Reference
Carboxyl . . . . .	$\text{CH}_2=\text{CH}-\text{COOH}$	Acrylic acid (24)
Aldehyde . . . . .	$\text{CH}_2=\text{CH}-\text{CHO}$	Acrolein (25)
Acetyl . . . . .	$\text{CH}_2=\text{CH}-\text{CO}-\text{CH}_3$	Methyleneacetone (26)
Acetoxy . . . . .	$\text{CH}_2=\text{CH}-\text{O}-\text{CO}-\text{CH}_3$	Vinyl acetate (27)
Ethoxy . . . . .	$\text{CH}_2=\text{CH}-\text{O}-\text{CH}_2-\text{CH}_3$	Vinyl ethyl ether (28)
Chloride . . . . .	$\text{CH}_2=\text{CH}-\text{Cl}$	Vinyl chloride (29)

Certain substituents have a definite effect in the ethylene group and greatly lessen the tendency to polymerize.<sup>20</sup> A methyl group on the ethylene has a pro-

<sup>25</sup> E. Baumann, *Ann.*, 1872, 163, 308; *Chem. Zentr.*, 1873, 28. See Chapter 51.

<sup>26</sup> R. Kuhn and A. Winterstein (*Helv. Chim. Acta*, 1928, 11, 87; *Chem. Abs.*, 1928, 22, 1767) have shown that the union of the end valencies of butadiene and isoprene with a phenyl group destroys completely the tendency to polymerize, and allows the study of these polyenes. They prepared a series of derivatives from stilbene ( $\text{C}_6\text{H}_5-\text{CH}=\text{CH}-\text{C}_6\text{H}_5$ ) to diphenyl hexadecaoctaene ( $\text{C}_6\text{H}_5-\text{CH}=[\text{CH}-\text{CH}]_7-\text{CH}-\text{C}_6\text{H}_5$ ). For the influence of carboxyl and carbalkoxyl groups in butadiene and their influence on polymerization, see K. Vogt, *Mitt. schweizerischen Kohlenforsch. Kaiser-Wilhelm Ges.*, 1925, 2, 69; *Chem. Zentr.*, 1926, 1, 2340; *Chem. Abs.*, 1927, 21, 3890.

found effect:  $\alpha$ -methylstyrene<sup>21</sup> forms an octamer whereas  $\beta$  methylstyrene<sup>22</sup> yields

only the dimer. Substituents in the phenyl group have little or no effect.<sup>23</sup>

The ethylene group may exist in a ring and still retain its ability to polymerize. Thus, cumarone,<sup>24</sup> indene,<sup>25</sup> cyclopentadiene<sup>26</sup> and pyrrole<sup>27</sup> will form polymers but do not build giant molecules.

pyrrole

#### MECHANISM OF ADDITION POLYMERIZATION

The reaction mechanism of addition polymerization may most easily be shown by the migration of a hydrogen atom:

Partial credence to this hypothesis has been given by the isolation of diindene of the structure<sup>28</sup>

which one may consider to have been formed by the wandering of a hydrogen atom.<sup>39</sup> The continual action of the molecules of the unsaturated polymer would ultimately give rise to a long chain molecule or macropolymer.

Chalmers<sup>40</sup> has pointed out that the stepwise theory of polymerization is quite inadequate to explain macropolymerization. If the rate of consecutive reactions in a polymerization is not greater than dimerization, it naturally follows that the dimer and other low polymers should be formed in the largest proportion. Moreover it should be possible to isolate the intermediate di-, tri- and tetramers during a reaction macropolymerization. The absence of lower polymers at the beginning of and during the reaction has been noticed by Stobbe and Posnjak<sup>41</sup> in the conversion of styrene, by Stobbe and Lippold<sup>42</sup> in regard to ethyl itaconate and by Lebedev and Mereshkowski<sup>43</sup> in the polymerization of diolefinic hydrocarbons.

The mechanism postulated for polymerization reactions is as follows.<sup>44</sup>

The reaction rate of this instance is comparable with those of the ordinary reactions of organic compounds. The following reaction, leading to the polymeric form is practically instantaneous:

A somewhat similar proposal has been made by Staudinger<sup>45</sup> wherein each of the polymers has free terminal bonds (free radicals) and the reaction is imagined to proceed at a very rapid rate.

<sup>39</sup> G. S. Whitby and M. Katz, *Can. J. Research*, 1930, 4, 344; *Chem. Abs.*, 1931, 25, 3988; *J.A.C.S.*, 1929, 51, 2548.

<sup>40</sup> W. Chalmers, *J.A.C.S.*, 1934, 56, 912.

<sup>41</sup> H. Stobbe and G. Posnjak, *Ann.*, 1909, 371, 269, 295; *Chem. Abs.*, 1910, 4, 2120.

<sup>42</sup> H. Stobbe and A. Lippold, *J. prakt. Chem.*, 1914, 90, 336; *Chem. Abs.*, 1915, 9, 209.

<sup>43</sup> S. V. Lebedev and B. K. Mereshkowski, *J. Russ. Phys.-Chem. Soc.*, 1913, 45, 1357; *Chem. Abs.*, 1914, 6, 320.

<sup>44</sup> W. Chalmers, *Can. J. Res.*, 1932, 7, 113.

<sup>45</sup> H. Staudinger, *Ber.*, 1920, 53, 1081.

The linking of the monomeric units would be expected to proceed at a rate which would be almost instantaneous as compared with that of activation. With very great chains, the rate should be increasingly slow. The macropolymerization of butadiene and other diolefins would be through the formation of pseudo-molecules of the type

In certain instances in the polymerization of diolefins where the action is catalyzed by an alkali metallic compound (R-K), the reaction may be explained by the hypothesis that the primary compound

is in itself an alkali metallic compound and can react with a molecule of butadiene to yield

and the process continues.<sup>46</sup> In this instance the potassium alkyl acts as a trigger for polymerization.<sup>47</sup> The polymerization of vinyl acetate follows a unimolecular rate. Benzoyl peroxide acts as a trigger catalyst.<sup>48</sup>

Tammann and Pape<sup>49</sup> studied the effect of pressure on the polymerization of styrene, isoprene, vinyl acetate, dimethylbutylene and indene. In these polymerizations there is first a decrease in volume. The decrease in pressure at constant volume was taken as a measure of the reaction velocity and it was found that the reaction behaved unimolecularly. The pressure-temperature curves show first a linear rise, then a break where polymerization begins, a sharp fall during polymerization, whereupon there is another rise due to the expansion of the polymer. Increasing pressure causes a decrease in the temperature at which polymerization occurs.

Starkweather<sup>50</sup> also studied the polymerization of a number of compounds at high pressures (2000-9000 atmospheres) at a temperature of 20-74°C. Among the compounds subjected to pressure were 4-iodo-1,2-butadiene, 2-bromo-1,3-butadiene, 2-chloro-1,3-butadiene, methyl vinyl ketone, 2-phenyl-1,3-butadiene, 1,4-dichloro-2,3,5-hexatriene, divinylacetylene, 2-heptyl-1,3-butadiene, styrene, isoprene, methylethylvinylethynylcarbinol and the like. The rate of polymerization by substituent groups in the  $\beta$ -position of the dienes is in the order of alkyl, phenyl, chloro, bromo and iodo. In the  $\alpha$ -position, the halogens are less effective whereas the alkyl groups are inhibitory.<sup>51</sup> Samples of cracked gasoline under high pressure gave no indication of any resinous products although the distillation range indicated that about 10 per cent of the low-boiling material had been converted into higher-boiling compounds.<sup>52</sup> A series of experiments with tung oil revealed that polymerization occurred at 500-600 atmospheres and 50°C. to yield products similar to those formed at much higher temperature at atmospheric pressure. Tung oil under pressure for three hours became more viscous. Longer subjection to

pressure caused the sample to become more gelatinous; ultimately a waxy gel was obtained which was somewhat drier than that obtained by ordinary heating.

One of the methods for following the course of a resin reaction of this type is the change in refractive index. During polymerization the unsaturation disappears and inasmuch as refraction is a function of unsaturation, a polymerization reaction would cause a lowering of the refractive index. Condensation reactions take place without the disappearance of unsaturation and no such lowering of the refractive index would be expected. Phenol-formaldehyde reactions are of the condensation type inasmuch as the refractive index increases with time. In styrene and tung oil the refractive index decreases.<sup>55</sup>

Katz<sup>54</sup> applied x-ray diffraction methods<sup>56</sup> to the study of polymerization. In many substances, styrene, indene, tung oil, isoprene, dimethylbutadiene, erythrene, the diameter of the diffraction ring was the same for the unpolymerized substance and for the polymerized derivative. On the other hand, ethyl cinnamate, methyl-ethylketone and methyl acrylate on polymerization showed considerable change in the diffraction pattern. Clark,<sup>56</sup> however, found that with tung oil an additional new ring of small diameter, that is, of large spacing, often appeared. Monomolecular dihydroxyacetone prepared by distillation of the dimolecular form was monomolecular as determined by cryoscopic measurements and gave a characteristic x-ray pattern. After the crystals had stood for several days, the diffraction pattern resembled that obtained by the dimolecular form even though molecular weight determinations still revealed only the monomolecular form.<sup>57</sup>

#### CATALYSIS OF ADDITION POLYMERIZATION

Catalysts exercise a profound effect on polymerization processes but their individual effect is not well understood. The more important catalysts for the polymerization of unsaturated compounds<sup>58</sup> include strong acids (sulphuric, hydrofluoric, phosphoric), anhydrous inorganic halides (aluminum chloride or bromide, ferric chloride, stannic chloride, antimony pentachloride), certain oxygenated substances (benzoyl peroxide, ozonides and oxygen) and highly absorbent materials (Florida earth, activated charcoal).

The effectiveness of a catalyst is assisted by heat to a certain extent depending on the stability of the polymer at any definite temperature. Catalysts lower the limit of stability, thus styrene undergoes the same polymerization in the cold in the presence of stannic chloride that it does at 270°C. by heat alone.<sup>59</sup>

The catalytic action of the inorganic halides is probably due to the ready formation of double compounds between the halides and the unsaturated substance undergoing polymerization. Hunter and Yohe<sup>60</sup> have suggested that an activated complex is formed in which one of the carbon atoms momentarily possesses a co-valency of three. Such a complex would be an excellent catalyst for polymeriza-

tion because it could immediately combine with another molecule of olefin. The new complex with a higher carbon content would still be in an activated state so that a long chain of carbon atoms might result by the interaction of incoming olefin molecules with those already present in the activated chain.

#### POLYMERIZATION OF THE DIOLEFINS

Of the diolefin hydrocarbons, those possessing a conjugated system of double bonds are of great interest because of their marked reactivity, polymerizing not only under the influence of heat but also with catalysts to yield substances of widely different properties.<sup>61</sup> Two types may be differentiated, the lower oily polymers of an unsaturated nature and macropolymers closely allied to rubber. (See Chapter 9.)

The lower oily polymers are usually cyclic hydrocarbons. Though unsaturated, the continued polymerization of these substances apparently does not result in the production of rubber-like polymers. This indicates that the unsaturated compounds can not be regarded as intermediates in the synthesis of the macropolymers. The dimers of the lower conjugated diolefins appear to be vinylcyclohexenes. Isoprene is known to yield at least two dimers

according to whether addition occurs to one or the other double bond of the isoprene.<sup>62</sup>

The formula assigned by Staudinger<sup>63</sup> to rubber is a linear structure of the type:

where the structural unit, or repeating pattern, is the active form of isoprene. On heating or by treatment with sulphuric acid, a cyclic product is supposed to be formed. This change is regarded as accounting for the alteration which occurs in rubber by treatment with vigorous reagents.<sup>64</sup>

Examination of unstretched rubber by x-rays reveals only an amorphous ring; stretched rubber, however, yields a sharp fiber diffraction pattern.<sup>65</sup> During the stretching process, rubber undergoes transformation from an amorphous to a crystalline state. This change is explained as follows: When rubber is stretched, the coiled chains pull out and cling together to yield long thin crystallites parallel to

<sup>61</sup> See E. N. Gapon, *J. Russ. Phys.-Chem. Soc.*, 1930, 62, 1385; *Brit. Chem. Abs. A*, 1931, 45, for a theoretical discussion of the polymerization of diethylenic compounds on the basis of a tervalent carbon. The energy necessary for this process represents the energy of activation.

<sup>62</sup> G. Egloff, M. Herrman, B. L. Levinson and M. F. Dull (*Chem. Rev.*, 1934, 14, 287) have reviewed the thermal reactions of isoprene and other terpene hydrocarbons.

<sup>63</sup> H. Staudinger, "Die hochmolekularen organischen Verbindungen—Kautschuk und Cellulose." J. Springer, Berlin, 1932, 380. See Chapter 54.

<sup>64</sup> See Chapter 54.

<sup>65</sup> J. R. Katz, *Chem.-Ztg.*, 1925, 49, 353; *Chem. Abs.*, 1925, 19, 2144.

the direction of stretching and are analogous to the long thin crystallites of silk, cellulose and wool to be mentioned later.<sup>66</sup>

The presence of the double bond in rubber brings about the possibility of stereoisomerism not only of "cis" and "trans" forms but of both.

The data from x-rays favor the "cis" form.<sup>67</sup> A large model arranged in the "cis" form can be coiled up into a cylindrical spiral and this spiral can be stretched out into a long chain. Swelling in solvents is attributed to the effect of solvent molecules which force themselves between the turns of the spiral and become attached to residual valencies causing a lengthening of the main valency chain. Vulcanization effects a union between the rubber spiral chains by sulphur bridges. A large amount of sulphur, however, causes the structure to be rigidly linked together.<sup>68</sup>

Staudinger<sup>69</sup> considers rubber to be a trans compound and balata to be a cis-derivative.

Further differences occur between these two compounds other than the stereo-

<sup>66</sup> W. E. Singer, J. D. Long and W. P. Davey (*Physical Rev.*, 1933, (2) 44, 319; *Brit. Chem. Abs. B*, 1935, 153) have shown by means of x-ray diffraction studies that there is a time lag between the time rubber is stretched and the time the fiber structure is produced. The phenomenon of time lag has been explained on the basis that rubber consists of a tangle of spiral or "zig-zag"-shape molecules with firmly fixed ends, the lengths of which can be temporarily untangled by the application of an external force.

<sup>67</sup> E. Mack, (*J.A.C.S.*, 1934, 56, 2766) has discussed the various factors which influence "cis" and "trans" addition in the formation of rubber and gutta-percha.

<sup>68</sup> H. Fikentscher and H. Mark, *Kautschuk*, 1930, 6, 2; *Brit. Chem. Abs. B*, 1930, 249. See K. H. Meyer and H. Mark, *Ber.*, 1928, 61, 1939; *Brit. Chem. Abs. A*, 1928, 1252. Celluloid is a perfect analogy for rubber. In the unstretched condition the x-ray diffraction pattern yields an amorphous scattering due to the fact that the camphor swells up the nitrocellulose. On stretching the celluloid, the camphor is expelled from the fiber structure and the nitrocellulose pattern can again be obtained. See K. H. Ueda, *Z. physik. Chem.*, 1928, 133, 350; *Brit. Chem. Abs. A*, 1928, 818.

<sup>69</sup> H. Staudinger, *Kautschuk*, 1934, 10, 6. *I. R. I. Transactions*, W. Heffer and Sons, Ltd.; Cambridge, 1935, 10 (3), 263. See H. Staudinger and H. F. Bondy, *Ann.*, 1929, 468, 1; *Chem. Abs.*, 1929, 23, 3372. Cf. D. K. Memmler, "The Science of Rubber," trans. D. F. Dunbrook and V. N. Morris, Reinhold Publishing Corp., New York, 1934.

chemical arrangement; the molecular weight of balata is much smaller. Mastication of rubber results in a shortening of the molecule. The smaller molecular weight would account for both the increased solubility and decreased swelling of the masticated form. (See Table 5).

TABLE 5.—*Rubber and Balata.*

Compound	Number of Isoprene Units	Molecular Weight	Length of Molecule in Å.u
Rubber, benzene soluble.	1300	88,000	5800
Rubber, ether soluble	930	64,000	4200
Masticated rubber . .	300	20,000	1350
Balata . . . . .	590	40,000	2650
Decomposed balata	100	6,800	450

The molecular weights of rubber and balata and of masticated rubber agree in order of magnitude with the particle size deduced by osmosis.<sup>70</sup> It appears, therefore, that osmotic pressure determinations do not determine the micelle weight of rubber but actually the true molecular weight.

Rubber is particularly sensitive to oxygen. Staudinger considers that rubber decomposes according to the following reaction scheme:

It can thus be readily seen that a very small quantity of oxygen can cause a great change in the physical properties. This reaction takes place in solution. In the solid state, however, the oxygen acts in such a way as to form oxygen bridges between the thread-like molecules.<sup>71</sup> Because of this action rubber of unlimited swelling capacity is converted into a rubber of limited swelling capacity. On this basis, the conversion of rubber from the soluble to the insoluble variety is therefore not a colloid chemical action but wholly a chemical action by which 3-dimensional macromolecules are formed from thread-like molecules.

#### CONDENSATION REACTIONS

In a condensation reaction, the polymer is no longer a multiple of the monomer as in the case of the addition polymer. During the reaction no addition of the reactants occurs but simple molecules such as water, alcohol, hydracid, sodium chloride are eliminated. In the final condensate, therefore, it is necessary to subtract the sum of the atoms liberated in order to determine the structural formula.

Single condensations do not yield a substance with resinous properties. In order to build up a large molecule, the reacting molecule must have more than one grouping to allow a multicondensation to take place.

In this instance, a condensation has taken place but no polymer results. With two reacting groups, or as they are more usually termed, functional groups, several reactions may take place: 1) intramolecular condensation:

<sup>70</sup> W. A. Caspari, *J.C.S.*, 1914, 105, 2139. K. H. Meyer and H. Mark, *Ber.*, 1928, 61, 593. H. Kroeplin and W. Bumshagen, *Ber.*, 1928, 61, 2441. W. Ostwald, *Kolloid.-Z.*, 1929, 49, 60.

<sup>71</sup> See H. Staudinger and H. F. Bondy, *Ann.*, 1933, 488, 153. Cf. three-dimensional polymers in this chapter.

2) the reaction may be intermolecular to build up a long chain and then become intramolecular

or 3) the reaction may be wholly intermolecular and yield a linear polymer

The question naturally arises as to just when intermolecular condensation takes place in preference to intramolecular condensation. Carothers<sup>73</sup> has developed a general rule to the effect that when the number of molecules in a unit chain is five, the product is monomeric and cyclic; if the number is six, the product may be either mono- or polymeric and if the number is greater than six, it is exclusively polymeric. In other words when stereochemically possible, cyclization will take place but this will only occur when the functional groups are very close together in the same molecule. When sufficiently separated, intermolecular reaction is to be expected.

This is at first difficult to reconcile with Ruzicka's<sup>74</sup> discovery that high-membered cyclic compounds can be prepared and are in no way less stable than smaller ones. That the rings are non-planar and strainless<sup>74</sup> can be seen on the basis of the Sachse-Mohr<sup>75</sup> theory inasmuch as there is a free rotation around each single bond in the chain; the 5-membered ring is planar and free from strain; the 6-membered ring is highly strained unless two of the atoms are on a different plane from the other four; larger-membered rings possess a marked mobility and can assume a multiplicity of shapes. X-Ray measurements reveal that these molecules contain double chains.<sup>76</sup>

These many-membered rings prepared by intramolecular reaction appear to be a peculiar phenomenon in that they are formed more through the accidental approach of the terminal groupings. The more general reaction is the intermolecular reaction.

#### TYPES OF MULTICONDENSATION

In the case of addition polymerization, it will be recalled, there were two types of addition: one the homo- and the other co-polymerization. Analogous types exist in multicondensation reactions, and they may be expressed as follows:

An example of the different types of condensation can be seen in the formation of polyesters. The hydroxyl and carboxyl group may exist in the same molecule and lead to a homo-condensation or the hydroxyl groups may exist in one molecule

<sup>73</sup> W. H. Carothers, *Chem. Reviews*, 1931, 8, 353.

and the carboxyl groups in another. In both instances, esters will be formed but they will differ in arrangement.

Numerous other types of condensation-polymerization exist and these may be summarized as follows. Long chain paraffins can be built up by the action of sodium on the polymethylene bromides followed by reduction in order to replace the terminal halogens by hydrogen.<sup>77</sup>

A bi-functional Friedel and Crafts<sup>78</sup> reaction, leading to the formation of polymerized material, can be seen in the action of aluminum chloride on benzyl chloride:

Other reactions yielding linear polymers by condensation include formation of polyamides,<sup>79</sup> polyamines,<sup>80</sup> polyacetals,<sup>81</sup> polyanhydrides,<sup>82</sup> polymethylene sulphide iodides,<sup>83</sup> aniline black,<sup>84</sup> polyphenylene ethers<sup>85</sup> and many many others which will be discussed in the following chapters.

#### STRUCTURE OF POLYMERS

When the colloid chemist dealt with the so-called "bio-colloids," he used the empirical concepts of "particle size" and "micellar structure" and regarded molecular weights and molecular individuality with considerable skepticism. One of

the earlier explanations offered was that proposed by Ostwald<sup>86</sup> who observed that these high-molecular-weight substances went through physical changes akin to dispersoids and called them "isocolloids."<sup>87</sup> Krumbhaar,<sup>88</sup> Wolff,<sup>89</sup> Scheiber,<sup>90</sup> Auer<sup>91</sup> and Wornum<sup>92</sup> have used colloidal concepts in an attempt to explain the reactions which occur in drying oils.

The continued interest in such substances as rubber, resins, cellulose, cellulose derivatives, starches, proteins and also in the synthetic resins has brought divergent views concerning their structure. These derivatives can be represented very simply by the empirical formulas:

where "n" indicates not only an unknown magnitude but also an unknown quality or kind of aggregation by which the units are united.

At least three different concepts have been utilized in an attempt to explain the manner in which these basal or structural units are united. The first, with which Staudinger's<sup>93</sup> name is associated, is that the structural units are bound together by the primary valences of the orthodox organic chemistry. Opposed to this theory are those of Hess and Pringsheim<sup>94</sup> and of Bergmann.<sup>95</sup> They are known as the association and the co-ordination theories respectively. Hess and Pringsheim believe that the unit structures are monomeric or dimeric and are held together by secondary valence forces or by association. Bergmann's theory is that the structural unit is co-ordinated in the solid state and the unit, as such, is incapable of free existence in the vapor phase or in solution. Polysaccharides and proteins are thus built up of small units associated in the large molecules by supermolecular affinities similar to that of molecules in a crystal lattice. The structural unit, as in the crystal, loses its independence and individuality, as such, within the larger aggregate.

Following the establishment, by x-rays, of definite periodicity in such substances as rubber, cellulose,<sup>96</sup> polycyclopentadiene<sup>97</sup> and polyoxymethylene,<sup>98</sup> Mark and Meyer<sup>99</sup> proposed their "micellar" theory where the high molecular weight organic compounds are considered to be linked together into chains by primary valence forces. Bundles of these chains are associated laterally by secondary valences to form micelles which act as entities and are responsible for the colloidal properties.

No attempt will be made to evaluate the experimental results on which the

individual theories have been based. Consideration will be given, however, to the primary valence theory inasmuch as it appears useful in predicting properties.

According to Staudinger the molecules are long thread-like chains of the monomeric groups linked together by primary valence bonds. As the degree of polymerization becomes greater, the molecular weight increases and the length of the chain likewise increases. The chain is in effect a single molecule and the properties of the polymer depend on the length of the chain. When the length of the chain is relatively short, hemi-colloids are obtained. Longer chains lead to "eucolloidal" properties.

In hemi-colloids, the mean molecular weight varies from 2000-10,000 and the single molecule consists of approximately 50-100 monomeric units. It is to be understood of course that in no instance are the chains in any one product of the same length, consequently both the molecular weight and the number of structural units must be an average figure. Solutions of hemi-colloids show relatively low viscosity and after the solution has been heated, the viscosity is not materially altered. The thermal softening point of the hemi-colloid is relatively low and the substance tends to be precipitated as an amorphous powder from solution upon addition of a nonsolvent.

Eucolloids<sup>100</sup> consist of molecules which are much longer than those of hemi-colloids. The mean molecular weight varies from 10,000 to well above 100,000 and the chain may consist of as many as 3000 monomeric units. The thermal softening point of the eucolloid is high and the substance, in contrast to hemi-colloids, is precipitated from solution as a material of a more or less fibrous nature. In solution, eucolloids have a high viscosity—a property which may be lowered by heat treatment. At the higher temperature, the longer chains are unstable and decompose into somewhat shorter ones.

When eucolloids do form, they are the end-products of a reaction which has taken place at a relatively low temperature. The lower the temperature, the greater tendency there is for the formation of the eucolloid. This is because the chain is sensitive to heat and the higher the temperature the shorter the chain.<sup>101</sup> Catalysts have the same effect as increase in temperature; rapid polymerization produces the hemi-colloid; slow polymerization yields the eucolloid.<sup>102</sup>

The polymerization of unsaturated compounds to a long thread-like chain leaves the end groups unsaturated:

These ends are troublesome to account for and various methods have been suggested to overcome the anomalously resulting structure. Conceivably the free radicals may be oxidized or otherwise converted to saturated groupings or the ends may combine with the molecules of the solvent.

<sup>100</sup> H. Staudinger (*Ber.*, 1934, 67, 1255) discusses the origin of the term "eucolloid."

<sup>101</sup> It is usually considered that at sufficiently high temperature decomposition to the monomer results.

There is a question, however, as to whether this is always true. F. O. Rice and K. K. Rice have recently reviewed the manner in which the various high polymers would be expected to behave on decomposition. See "The Aliphatic Free Radicals," The Johns Hopkins Press, Baltimore, 1935, 142 seq.

<sup>102</sup> W. H. Carothers and J. W. Hill (*J.A.C.S.*, 1932, 54, 1587) found that the linear polyesters in spite of the high molecular weights are formed at 200-250°C. and show no sign of being degraded by repeated exposure to high temperatures.

Moreover, the free ends might combine intramolecularly to form rings.

Carothers,<sup>108</sup> however, does not consider such large ring structures feasible. In any polymerization, be it condensation or addition, the reaction must be step-wise and consequently ring closure if it is to take place must occur as the last step in the reaction. The longer the chain, however, the more distant the ends must be and the less opportunity there is for ring closure.

The relation between the solubility and the length of chain is not easily discernible. Some molecular chains of great length are soluble whereas others of relatively short length are insoluble. Polystyrene, consisting of perhaps a thousand structural units is soluble but one form of polycyclopentadiene, containing 6 pentadiene units per molecule is insoluble. Polystyrene consists of a long saturated chain with phenyl groups hung along this chain at each alternate carbon and tends to form only linear chains

Polycyclopentadiene<sup>104</sup> may undergo secondary polymerization between the remaining double bonds resulting in an irregular molecule

Linear structures have been suggested for other macropolymers:

<sup>108</sup> W. H. Carothers, *Chem. Reviews*, 1931, 8, 379.

<sup>104</sup> See Chapter 9 for another version of the structure of polymerized cyclopentadiene.

### THREE-DIMENSIONAL POLYMERS

The distinct illustration of the possible relation between chemical structure and solubility is shown in the glycol and glycerol phthalates. Glycol phthalate can form only linear polyesters by multicondensation and tends to remain soluble in all stages.<sup>109</sup> Glycerol phthalate, on the other hand, can grow in more than one direction and as the size of the molecule becomes greater, it also becomes more complex and compact with the result that the solubility and fusibility decrease.

Moreover, wherever a double bond or other sensitive point occurs in the chain, the tendency is toward the formation of insoluble products. This apparently is due to cross-linkages between the chains. If "A" represents a monomeric group containing a double bond or other sensitive group, the action may be expressed:

For example one may consider two molecules of Bakelite A yielding the insoluble and infusible Bakelite C.<sup>110</sup>

<sup>109</sup> See Chapter 41 and *seq.*

<sup>110</sup> On the following page is given the manner in which A. E. Blumfeldt (*loc. cit.*) represents the formula giving the impression that the molecule is aromatic. Actually the compound as worked out on his basis is hydraromatic, and also contains terminal hydroxyl groups. M. Koebner (*Chem.-Ztg.*, 1930, 54, 619; *Chem. Abs.*, 1930, 24, 6039) has criticized Blumfeldt's formula because it fails to account for the presence of hydroxyl groups.

Bakelite C.

Cross-linkage of molecular chains can be accomplished through the addition of other reagents. Resins of this type are known as element-convertible and include blown oils, olefin-sulphur resins and the unsaturated acid-modified glycerol-polybasic acid resins. See Table 6.

Certain other features distinguish the linear from the three-dimensional polymer. The 2, 2<sup>111</sup> type of polymer (cellulose, rubber, polyoxymethylene, glycol-polyesters) on x-ray examination reveals a pseudo-crystalline or fibrous structure whereas the 2, 3 (or greater) type of polymer (glycerol phthalate, Bakelite) reveals more of the amorphous structure.<sup>112</sup>

TABLE 6.—*Synthetic Resins and Their Polymers* \*

Reacting Molecules	Reactivity	Preparation	Length of Chains	Mol. wt.	Type Resin
Styrene.....	2 2	Heat	Long	Very high	Non-convertible
Formaldehyde.....	2 2	Heat	Long	Very high	Non-convertible
Cyclopentadiene.....	2 2	Heat	Long	High	Non-convertible

Drying oil oxygen....	(6-8) 2	Heat pressure	Short twining	Moderate	Convertible

\* R. H. Kienle, *Ind. Eng. Chem.*, 1930 22, 592.

Moreover certain correlations may tentatively be made between the distances between the reactive groups which are involved in cross-linkages and in the hardness of the resin.<sup>113</sup> If the distance between the reactive groups is great, that is, there are many saturated points between them, the cross-linkages must of necessity be widely apart; consequently the macromolecule will tend to be of an open structure and will be soft and possess a low melting point. The more rigid and compact the molecule is, due to many cross-linkages, the higher will be the melting point. The concept has been offered as an explanation for the hardness of phthalate resins as compared with citrate resins of the alkyd type. The glycol phthalate resins exhibit a similar phenomenon; ethylene glycol (HO-CH<sub>2</sub>-CH<sub>2</sub>-OH)

<sup>111</sup> The 2,2 type of polymer is one in which only two functional groups react to form a polymer. Thus in the case of the glycol polyesters, there are two reactive groupings in glycol (HO-CH<sub>2</sub>-CH<sub>2</sub>-OH) and two reacting groupings in the acid (HOOC-R-COOH). When glycol reacts with a dibasic acid, molecular growth can only occur in one direction and only a linear polymer can result. Glycerol, however, containing three hydroxyl groups, can grow in other directions than in the linear form. In other words, the functional activity of glycerol is three.

Cellulose is considered as a 2,2 polymer even though the glucopyranose from which it is derived has a functional reactivity of 5. Only two of the five functional groups are involved in the formation of the polymer.

<sup>112</sup> See R. H. Kienle, *Ind. Eng. Chem.*, 1930, 22, 592. For further discussion, see latter part of this Chapter.

<sup>113</sup> N. Tsonev and N. Yavnel (*Masloboina Zhirovoe Delo*, 1932 (9), 28; *Chem. Abs.*, 1933, 27, 3471) have suggested that the hardest resins are obtained from the least symmetrical molecules. Cf. Chapter 24.

forms a hard glassy resin; propylene glycol ( $\text{HO}-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{OH}$ ) yields a product which is less hard and possesses a lower melting point; whereas diethylene glycol ( $\text{HO}-\text{CH}_2-\text{CH}_2-\text{O}-\text{CH}_2-\text{CH}_2-\text{OH}$ ) gives rise to a product of balsam-like properties.<sup>114</sup>

Essentially the same relation exists in the condensation products of aminoaryl-sulphonamides and aldehydes.<sup>115</sup> Hardenability depends not so much on molecular magnitude as upon the constitution of the resin with respect to ring closure and cross-linkages. Hardenability is not observed in the aminoarylsulphonamide condensation product with formaldehyde, even when the number of amino groups is sufficient for the purpose, if either one or the other amino group does not react with the aldehyde or if molecular association is impeded at one of the two positions. Excessive spatial proximity of the reactive groups (e.g., in the ortho position) is a barrier to reactivity. The primary condensation may take place but the second group does not react. Depending on the initial starting material and the choice of reaction conditions aniline mono- or polysulphonamides can be made to yield crystalline compounds or resins which belong to the fusible or infusible type. Condensations with benzaldehyde yielded crystalline derivatives; acetaldehyde and furfural gave rise to crystalline compounds or infusible resins whereas formaldehyde gave rise to all three varieties.<sup>116</sup>

From evidence obtained in glycerol-phthalic anhydride condensation and in the tung oil polymerization, Wornum<sup>117</sup> believes that at low temperature straight-chain reaction occurs to form a small number of large units. Under these conditions gelation occurs only upon long heating. At high temperature 3-dimensional growth occurs immediately, yielding a large number of small units. Cross-linkages occur rapidly, bringing about phase complexity and gelation. It appears that at low temperature the  $\beta$ -hydroxyl group is inactive and only the  $\alpha$ -hydroxyl groups react, consequently a linear polymer is obtained. At higher temperatures all three hydroxyl groups enter into the reaction.

A somewhat analogous situation exists when styrene and divinylbenzene are allowed to polymerize.<sup>118</sup> Styrene, as has been mentioned, gives rise to a linear polymer. Divinylbenzene, having two vinyl groups can build up a 3-dimensional polymer. Combination of styrene and divinylbenzene yields a compound whose general structure may be represented as follows:

<sup>114</sup> L. A. Jordan and J. O. Cutter, *J.S.C.I.*, 1935, 54, 89T.

<sup>115</sup> See Chapter 34.

<sup>116</sup> G. Walter and H. Pollak, *Kolloid-Beihfte*, 1934, 40, 1; *Brit. Chem. Abs. B*, 1934, 1020.

<sup>117</sup> W. E. Wornum, *J. Oil, Colour Chem. Assoc.*, 1933, 16, 231.

<sup>118</sup> H. Staudinger, *Kautschuk*, 1934, 10, 7.

The reaction between urea and formaldehyde may be considered to give rise to a 3-dimensional polymer.<sup>119</sup>

Houwink<sup>120</sup> has compared the gelatin gel with the urea-formaldehyde condensation product in its initial stages of formation. Both substances contain large amounts of water and form strongly lyophilic masses. Following the supposed reaction mechanism it can be seen how the presence of the hydroxyl groups in the dimethylolurea might be responsible for the hydrophilic properties of the gel. On heating and elimination of water with the formation of macromolecules, the hydroxyl groups would disappear with a corresponding reduction of the hydrophilic properties.

### NATURAL PRODUCTS

These linear polymeric representations of synthetic materials have lent definite support to similar structures assigned to natural products. This has already been partly shown in the case of rubber. Other natural products which have been analogously treated are cellulose, wool, silk and other proteins. As evidence continues to accumulate, there appears to be a most intimate relation between resins, rubber-like products and fiber structures.

Much of the work which has been carried out on rubber and on fibrous structures is of immense importance in the field of synthetic resins. Rubber at low temperatures is hard and brittle and it may be that rubber owes its chief virtue to the fortuitous circumstance of having elastic properties at room temperature. At high temperatures, rubber on treatment with air can be converted into a resin.<sup>121</sup> On the other extreme certain of the high-melting resins approach at high temperature the rubber-like state. Autopolymerized styrene behaves like raw rubber above 65°C.<sup>122</sup> Above this temperature, the styrene polymer may be "racked."<sup>123</sup>

Von Weimarn<sup>124</sup> has called attention to the fact that linear polymers such as rubber, silk, resins, lacs, lubricating oils and the like may exist in the mesomorphic state of matter.<sup>125</sup> According to Friedel,<sup>126</sup> there are sharp discontinuities between the liquid (amorphous phase), the nematic state (where the long molecules point in one direction but are not grouped into parallel planes), the smectic state (where the molecules are arranged in parallel planes) and the crystalline state (where the molecules are marshalled into a 3-dimensional pattern). An experiment of de Jong<sup>127</sup> is of interest in this connection. A thin film of gutta-percha hydrocarbon, obtained by slow evaporation of a benzene solution, consisted in microscopic rosettes of needles. After stretching, this film showed straight extinction with polarized light between crossed Nicol prisms.

<sup>119</sup> See Chapter 26.

<sup>127</sup> A. W. K. de Jong, *Rec. trav. chim.*, 1931, 50, 1011; *Brit. Chem. Abs. A*, 1931, 1421.

Another development is again due to von Weimarn.<sup>128</sup> He has succeeded in obtaining an unstable rubber-like substance from elementary sulphur. By pouring hot liquid sulphur at 400°C. in a thin stream into liquid air, solid and brittle threads are obtained; on warming, the threads acquire a high elasticity similar to that of rubber but the property disappears after a short time whereupon the sulphur becomes translucent and changes over to the normal viscous state.

Due to the rapid temperature drop of approximately 600°, some of the molecules become orientated whereas others form a highly disperse glass. As the temperature rises, the glass melts into a viscous liquid, yielding a system with the highly elastic properties of rubber.

Just what exact relation exists between fibers, resins and rubber is at present hypothetical. Resins may be an indiscriminate mixture of rod forms without any special attraction or repulsion in any one direction. In the case of fibers these same rods might be arranged parallel with attractive forces at the ends of the rod whereas in elastic substances there could be repulsive forces at the end of the chain so that they would attach themselves at right angles to one another. In such a state any deformation would cause the substance to return to its undeformed condition.<sup>129</sup>

#### CELLULOSE

The old micellar theory of von Nägeli<sup>130</sup> had postulated that in the cellulose fiber there were linear anisotropic micelles. Each individual micelle should behave as a small crystal. The theory was not accepted seriously. A great many years later, Ambronn<sup>131</sup> pointed out that, if cellulose were crystalline, it should reveal an x-ray pattern. His own studies on the accidental double refraction in celloidin (nitrocellulose) and in cellulose had indicated to him the essential truth of von Nägeli's theory of crystalline micelles. The strong dichroism shown by the natural fibers as well as by the permanently stretched celloidin appeared to be additional evidence.<sup>132</sup>

Both Scherrer<sup>133</sup> and Herzog and Jancke<sup>134</sup> almost simultaneously showed by x-ray patterns that cellulose was crystalline. Cotton, ramie, wood, artificial silk and viscose all revealed these patterns, moreover wood behaved similarly to cotton and ramie (see Fig. 5). It was further determined that the crystallites were parallel to one another and parallel to the crystallographic axis of the fiber.<sup>135</sup> Sponsler and Dore<sup>136</sup> then postulated the long chain structure for cellulose which together with the x-ray studies by Mark and Meyer<sup>137</sup> and Haworth's<sup>138</sup> proof of the structure of cellobiose and the relationships existing between glucose, cellobiose and cellulose have placed the polymeric linear structure beyond the hypothetical stage. Cellulose may now be considered to be built up of anhydroglucopyranoses as follows:

There is considerable disagreement as to the number of glucose units in the chain. Meyer and Mark<sup>139</sup> estimate that the number is from 60-100 (i.e., molecular weight from 10,000-16,000). Staudinger<sup>140</sup> is disposed to set the molecular weight much higher. Stamm,<sup>141</sup> however, by means of the ultracentrifugal method,<sup>142</sup> studied the nature of pure cotton linters ( $\alpha$ -cellulose) in cuprammonium solvent and obtained a value, on a copper-free basis of  $40,000 \pm 5000$ , indicating that the cellulose molecule is built up of 200-260 simple glucose units.

Haworth and Machemer<sup>143</sup> determined the length of the cellulose chain by strictly chemical means, namely by estimating the terminal groups. By completely methylating cellulose the end groups of the product should be tetramethylated whereas the glucose units in the chain would be trimethylated. On hydrolysis, one of the terminal groups would be isolated as a tetramethylglucopyranose, the other terminal group would be hydrolyzed into 2, 3, 6-trimethyl glucose and methyl alcohol. From the ratio of the trimethyl to the tetramethylated products it was possible to estimate the length of the cellulose chain. It was found by this means that cellulose consisted of not less than 100 and not more than 200  $\beta$ -glucose units. This corresponds to a molecular weight of 20,000-40,000 or a mean value of approximately 30,000.

The most widespread views concerning the structure of cellulose have been developed on the one hand by Staudinger and by Meyer on the other. Staudinger<sup>144</sup> undertakes to show that certain structural units under the influence of co-valencies align themselves in one direction to form a fiber-like structure. Meyer<sup>145</sup> believes that these linear polymers unite to form a bundle, or micelle, by means of reciprocal lateral attraction. Other materials than cellulose can participate in the formation of this bundle so that a "mixed micelle" comparable to a mixed crystal can develop.

There are two general types of reaction which cellulose can undergo and these have been called the "micellar surface" and the "permutoid" reactions. These reactions appear to depend on whether the reagent penetrates between the micelles without attacking the internal structure or whether the reagent penetrates the whole structure attacking specific chemical groupings at each point of the lattice.<sup>146</sup>

Although a large and definite part of the cellulose fiber is crystalline, there is a certain amount of amorphous material in the fibers and in other cellulose products such as ramie, hemp, sisal, jute, flax, cotton and wood.<sup>147</sup> (See Figs. 5 and 6.) The

<sup>147</sup> R. Thiesen (*Ind. Eng. Chem.*, 1932, 24, 1032) in a study of natural products by means of the Spierer lens has found that cotton and ramie are built up of micelles in characteristic arrangement. In semi-rotten wood, the cells are similar in arrangement but stand out more clearly than in decayed wood. The transition stages which occur between sound wood and semi-rotten wood indicate a close relationship between cellulose and lignin.

amorphous materials which may consist of resins, hemicelluloses and lignin do not interfere with the x-ray pattern. The crystalline part may be mercerized, nitrated, acetylated and treated chemically in the solid form and the resulting product is still a fiber crystal.<sup>148</sup>

According to von Weimarn,<sup>149</sup> it is possible to reduce cellulose to a plastic gel by treatment with aqueous saline solutions under appropriate conditions of pressure, temperature and concentration depending on the type of salt employed. Two extreme types of cellulose solution exist: (1) solutions containing elastic continuous jellies and (2) solutions failing to produce any aggregatory effect, or yielding precipitates. Between these types various intermediates exist. Cellulose jellies which have been washed to remove salts shrink rather rapidly, become denser and acquire considerable tensile strength. When completely dried, the jelly becomes brittle but preserves its tensile strength. The transition of cellulose jellies to plastics (in this case ointment-like masses) is dependent upon the concentration of products of cellulose hydrolysis in the gels. Beyond a certain concentration of such products, the properties of the jellies change from elastic systems into the region of plastic masses.

When cellulose is gelatinized in sodium hydroxide solution, heat is evolved; the amount increases with the concentration of caustic alkali.<sup>150</sup> The elasticity of these swollen fibers is comparable to that of rubber.<sup>151</sup>

### PROTEINS

The  $\alpha$ -amino acids, as is well known, are obtained by hydrolysis of proteins. These  $\alpha$ -amino acids contain bi-functional groups and would be expected to be linked up in the protein molecule as linear polymers, with the structural unit as the anhydro-amino acid.

Several of these reactions are known to occur. Glycine on heating in glycerol at 150-170°C. for 24-30 hours yields an amorphous polymer of the formula  $(\text{C}_2\text{H}_4\text{ON})$  which is reconverted to glycine by hydrolysis.<sup>152</sup> Moreover, glycine ethyl ester decomposes spontaneously, yielding glycol anhydride containing 4 unit groupings.<sup>153</sup> This reaction product may be expressed as:

Fischer's<sup>154</sup> famous synthesis of the octadecapeptide, l-leucyl-triglycyl-l-leucyl-triglycyl-l-leucyl-octaglycyl-glycine gave rise to a linear chain polymer of the same type:

Svedberg and co-workers<sup>154</sup> have elucidated to a great extent the molecular weights<sup>155</sup> of proteins by measuring sedimentation equilibrium in the ultracentrifuge and also by measuring the sedimentation velocity in a very much stronger cen-

trifugal field<sup>156</sup> (See Figs. 7, 8 and 9) It was found that proteins formed isodisperse particles, that is, of single molecular weight and that many of the proteins have molecular weights that are multiples of egg albumin.<sup>157</sup> (See Table 7.) By combining the determination of the sedimentation equilibrium and the sedimentation velocity, it is possible to obtain a measure of the deviation of the particle from the spherical shape. By means of these calculations, it was found that protein molecules with molecular weights of 1 or 6 times 34,500 are sensibly spherical whereas those of integrals 2 and 3 are presumably non-spherical.

<sup>154</sup> T. Svedberg and R. Fahrensen, *JACS*, 1926, 48, 430; and J. B. Nichols, *ibid.*, 1923, 45, 2910, and H. Rinde, *ibid.*, 1924, 46, 2677. For reviews on the method see T. Svedberg, "Centrifugal and Diffusion Methods for the Study of Dispersity and Hydration in Sols" in J. Alexander, "Colloid Chemistry," Chemical Catalog Co., Inc., New York, 1926, I, 838. See also T. Svedberg, *Chem. Reviews*, 1934, 14, 1. J. B. Nichols, *Ind. Eng. Chem., Anal. Ed.*, 1932, 4, 12. J. B. Nichols (*Nature*, 1930, 125, 814; *Chem. Abs.*, 1930, 24, 4202) compared the molecular weight determinations by ultracentrifugal measurements with ebullioscopic methods and found them to be sensibly co-ordinated. J. W. McBain, C. R. Dawson and H. A. Barker (*JACS*, 1934, 56, 1021) have studied the diffusion of colloids and colloidal electrolytes and especially egg albumin. From their work it appears as if diffusion through porous membranes was one of the simplest, quickest and most accurate methods of determining particle size or molecular weights. For egg albumin a value of 34,000 was obtained for the molecular weight at the isoelectric point. This compares well with the ultracentrifugal method. Other values of pH brought divergent results apparently due to mutual acceleration and retardation of ions.

<sup>155</sup> There is some question as to whether the determination under these conditions is actually the molecular weight or the weight of the separate particles or micelles.

<sup>156</sup> When a solution is centrifuged in a closed cell for a sufficiently long time, equilibrium results between sedimentation and diffusion. The time required for a quantity of the solute to be driven down by centrifugal force is then the same as that wandering in the direction of rotation through diffusion. To determine the molecular weight it is only necessary to measure the relation between the concentration of the solution at two points from the center of rotation. This value together with temperature, speed of the centrifuge, the partial specific volume of the solute and the density of the solvent allows calculation of the molecular weight.

The velocity of sedimentation may be obtained by using very much stronger centrifugal fields, that is, from 30,000 to above 400,000 times the force of gravity. (A field of 400,000 requires a rotor moving at 75,000 r.p.m.)

<sup>157</sup> W. T. Astbury and H. J. Woods (*Nature*, 1931, 127, 663; *Brit. Chem. Abs. A*, 1932, 752) considered the multiples in the polypeptides to be due to vibrational instability of peptide chains when they became greater than a certain limit.

FIG. 8.—A Super-centrifuge Used for Separation of Proteins.

Wool, without doubt, is also constructed from long polypeptide chains although much is not known concerning the structure.<sup>158</sup> Two important amino acids which are obtained from wool by hydrolytic cleavage are glutamic acid:

and arginine

These acids are polyfunctional and may induce cross linkages between the chains of the polypeptides forming a ladder-like structure.<sup>159</sup> This may be accomplished through a salt-like linkage

<sup>158</sup> W. T. Astbury and R. J. Woods, *J. Text. Inst.*, 1932, 23, 127; *Brit. Chem. Abs. A*, 1932, 451. See also W. T. Astbury, "The Fundamentals of Fibre Structure," Oxford University Press, London 1933.

<sup>159</sup> In muscle protein it has been considered that free acidic and basic groups exist in the chains. At the isoelectric point the  $\text{COO}^-$  and  $\text{NH}_3^+$  ions may attract and pull the chain into a spiral. This has been offered as a mechanism for muscular contraction. (See K. H. Meyer and H. Mark, "Der Aufbau der hochpolymeren organischen Naturstoffe," 1930, 238.)

or through a definite polypeptide linkage

Another important amino acid found in the hydrolytic products is cystine. This acid is likewise polyfunctional and can directly bring together two chains:

*Silk* differs from wool in that the amino acids obtained by hydrolytic cleavage contain no sulphur, in other words, cystine is not obtained. The chief amino acids found in silk fibroin<sup>100</sup> are glycine ( $\text{NH}_2\text{-CH}_2\text{-COOH}$ ), alanine ( $\text{CH}_3\text{-CH(NH}_2\text{)-COOH}$ ) and tyrosine ( $p\text{-NH}_2\text{-C}_6\text{H}_4\text{-CH}_2\text{CH(NH}_2\text{)-COOH}$ ). The formula for silk fibroin has been considered tentatively as follows:<sup>100a</sup>

Von Weimarn<sup>101</sup> disintegrated natural silk, coagulated and dried the coagulant. Instead of a flexible substance, he obtained a brittle resinous glass-like mass. The method of accomplishing this is as follows. Silk wadding was gradually added to hot aqueous sodium thiocyanate (86-120°C.) and the silk was dispergated under these conditions. After dialysis and subsequent standing the silk solidified to an elastic jelly, which, on further standing, developed syneresis and eventually yielded a perfectly solid glass.

The wet masses, however, could be pulled into threads, especially in the presence of aggregators. Those salts which readily dispergate silk are poor aggregators.

<sup>100</sup> For the studies on the colloidal behaviour of silk sericin, see H. Kaneko, *Bull. Chem. Soc., Japan*, 1934, 9, 207, 241, 283, 409, 344, 461, 510; *Brit. Chem. Abs.* A, 1934, 842; B, 1934, 878; A, 1934, 1069, 1172, 1306; 1935, 33, 165.

brittle thread resulted. On stretching and relaxing the thread several times before drying, silk threads were formed which appeared to surpass natural silk

### FIBER STRUCTURE

There is now almost conclusive evidence that materials which form threads and fibers are built up of molecules in which the length is very much greater than any other dimension. The analogy has been drawn to floating logs. Their natural orientation is that pointing down stream and they will travel in that position even if they enter in a random manner. Solutions of many highly polymerized compounds including rubber, cellulose derivatives and polystyrenes exhibit the phenomenon of streaming double refraction.<sup>152</sup> This same phenomenon is observed in sols which on stirring yield marked streaks and in liquids that are just beginning to crystallize and therefore contain very fine crystals.<sup>153</sup> Particles suspended in a streaming liquid have both translatory and rotational motion about their centers of gravity. Elongated particles tend to be oriented; this tendency, however, is opposed by the Brownian movement.<sup>154</sup> Kuhn<sup>155</sup> inferred that the flow double refraction of rubber, gelatin and polystyrene solutions occurs only when a flow gradient is set up. The disperse particles cannot be linear when they are at rest but are coiled up in such a manner that they become effectively isotropic.

Astbury and Woods<sup>156</sup> have deduced from x-ray investigation that fibers may exist in fully extended molecules in such compounds as cellulose, natural silk, stretched wool or hair and stretched rubber. "Folded" or coiled molecules exist in unstretched hair and rubber. X-Ray photographs of stretched hair yielded a diffraction pattern which resembled closely that given by natural silk at all

stages of extension. Other proteins which give similar diagrams are collagen in sinews<sup>107</sup> and to some extent in hide and gelatin.<sup>108</sup> Similarly, the photograph of rubber agrees with that which would be expected from polymerized isoprene in the form of chains extended in the direction of stretching. The extended molecules lack elasticity, and fibers built up from such molecules extend through "internal" slippage. Folded molecules can be unfolded allowing the fiber to expand, thus conferring considerable elasticity.

In wool, the change is from the folded keratin molecules (known as  $\alpha$ -keratin) into the longer molecules ( $\beta$ -keratin). The transformation of  $\alpha$ -keratin to  $\beta$ -keratin can be arrested by drying the wool just as it is possible to check the contraction of rubber by cooling. When this stretching process is carried out in boiling water or steam, an extension of something like 100 per cent takes place without rupture; under these conditions there is a complete transformation to the  $\beta$ -form. The skeleton of the unstretched keratin is considered to consist of a polypeptide chain folded into a series of hexagons which are in effect diketopiperazine rings. The rearrangement can be pictured as follows:

Mark<sup>109</sup> has made calculations as to the strength of textile fibers. Assuming that the fiber is made up of infinitely long chains and further assuming that the tensile strength represents the work necessary to break a primary valence bond, he arrives at a figure of 800 kg. per square millimeter for cellulose. This value is much too high. These chains, however, are not infinitely long and moreover the break may occur not through the severance of a primary bond but by the slippage of the chains which are held together by van der Waal's forces. This supposition still assumes that the fibers are in perfect orientation; local imperfections occur which lower this value markedly.

The similarity of silk and cellulose fibers in respect to tensile properties rests

on analogous constitution. Assuming the molar cohesion of glyceryl residues to be about 11,600 calories, a chain of 100 peptide units (length 350 Å. U.) would have a molecular cohesion of over  $10^6$  calories. This approaches the value of the cellulose chain.<sup>170</sup>

#### METHODS OF DETERMINING THE MOLECULAR WEIGHT OF POLYMERS

As has already been indicated, ultracentrifugal methods have been used for the determination of the molecular weight of the proteins. In this instance the proteins show uniform particles. Polymerization processes, however, yield a variety of products in the form of polymer homologues and inasmuch as no homogeneous substance is present, the molecular weight represents only an average value. When fractionation of the sample is achieved, there is a much closer approximation to a uniform product and the size of the molecule becomes a matter of considerable interest.

In many instances the size of the molecule and its structure may be partially determined through density, index of refraction, solubility and volatility in comparison with analogous compounds. The method consists in preparing a series of compounds having the same structural unit. From the lower more soluble polymers molecular weights can be obtained and results extrapolated to the higher values.

In the case of molecules of known basal units and known end groups but unknown chain length, it is possible to determine the molecular weight by estimating the end groups quantitatively. Further, knowing that there are two terminal groups in each molecule and with an exact knowledge of the molecular chain, its precise length may be calculated.

The relation between molecular weight and viscosity has yielded interesting results as developed by Staudinger.<sup>171</sup> Earlier experiments in this field were concerned more with low-molecular weight compounds;<sup>172</sup> Staudinger, however, worked with colloids and divided them into two classes on the basis of the viscosity. In one class were those colloids whose molecules were spherical, such as suspensoids and emulsoids. In the second class were included compounds which were non-spherical and were of fiber structure; this second class was further subdivided into association colloids and molecular colloids.

In the low-molecular-weight spherical molecules, the specific viscosity is independent of the molecular weight because this property depends on the number of particles in solution. Under these conditions Einstein's<sup>173</sup> rule is valid in that the viscosity depends wholly on the volume of the disperse phase, in other words, on the concentration. Long molecules behave differently, however. The viscosity

<sup>172</sup> For a consideration of this work see E. Hatschek, "The Viscosity of Liquids," G. Bell and Sons, London, 1926, Chapter 7.

<sup>173</sup> A. Einstein, *Ann. Physik*, 1906, (4) 19, 289; *Kolloid-Z.*, 1920, 27, 137.

of equally concentrated solutions is not constant but is proportional to the molecular weight. Inasmuch as the molecular weight is proportional to the length of the chain, the viscosity would increase with the length of the molecule and Einstein's rule would no longer hold. Moreover, a difference in the structure of association colloids and molecular colloids may be shown by the alteration of the viscosity of the association colloids on heating due to a disruption of the micellar structure. The long fiber molecules have an elastic structure due to the fact that they exist as a single entity bound by primary valence and on heating the specific viscosity is not altered. The relation between specific viscosity and molecular weight gives an insight into weight and also length of the macropolymers.

The specific viscosity (relative increase in viscosity caused by the solute) of carbon tetrachloride solutions of paraffins, aliphatic esters and ketones is given by the equation

$$\frac{\eta_{sp}}{c} = ny + x$$

where  $c$  = quotient of the concentration in grams per liter by 14, i.e., the molecular weight of the methylene,  $-\text{CH}_2-$ , group  $n$  = number of carbon atoms in the molecule,  $y$  is a constant characteristic of the methylene group and  $x$  a constant which is zero for paraffins but depends on the nature of the groups containing oxygen. For the equation to be valid,  $n$  must be greater than 9. In aliphatic acids it is not the number of carbons in the normal molecule but in the co-ordinated molecule which must be taken into consideration inasmuch as acid particles are present both in solution and in the crystal as co-ordinated double molecules.

In the case of alcohols, however, a lower value is obtained because both the normal (ROH) and the co-ordinated molecules (ROH·HOR) are present. The viscosity determination offers a means of measuring this dissociation. (See Fig. 10.)

Once the constants for the different series were known, a relationship was found between the various hydrocarbon polymers, namely, that equally concentrated solutions are built up of long fiber molecules of the same length whenever the specific viscosity of the solutions is the same. Structure and chemical behavior do not enter into viscosity, only the length of the molecule.

The equation therefore becomes

$$\frac{\eta_{sp}}{c} = Km M$$

where  $c$  is the "grundmolare Konzentration" or the concentration in primary mols.<sup>174</sup>  $M$  is the molecular weight,  $Km$  a constant and  $\eta_{sp}$ , the specific viscosity which is determined from the relative viscosity by the relationship

$$\eta_r - 1 = \eta_{sp}$$

<sup>174</sup> The concentration is expressed in terms of the repeating unit. In the case of polystyrene, the repeating unit is  $-\text{CH}_2-\text{CH}(\text{C}_6\text{H}_5)-$  of molecular weight 104. When  $c = 1$ , there will be 104 g. of the substance in a liter of solution, or  $c = 1$  for a 10.4 per cent solution. The  $km$  constant for the lower fractions of polystyrene polymers was found to be  $1.8 \times 10^{-4}$ . (See Table 8.) Substituting in the equation  $\eta_{sp}/c = Km M$ , the values become  $0.11/0.001 = 1.8 \times 10^{-4} M$ , or  $M = 6.1 \times 10^5$ . For the anomalies which appear in more concentrated solutions of polystyrenes see H. Staudinger and R. Nodsu, *Ber.*, 1930, 63, 717; *Chem. Abs.*, 1930, 24, 717 and H. Staudinger and W. Heuer, *ibid.*, 222; *Chem. Abs.*, 1930, 24, 5716.

The relative viscosity is in turn derived from the relation where the  $t$  (time) is determined from viscosimeter determinations

$$\eta_r = \frac{t \text{ (solution)}}{t \text{ (solvent)}}$$

Ring structures, however, markedly affect the viscosity;<sup>175</sup> thus, solutions of cellulose derivatives are more viscous than solutions of rubber or hydorrubber with

FIG 10

Relation Between Viscosity and Chain-Length of Paraffins and Paraffin Derivatives in 14 per cent Carbon Tetrachloride Solution.

Courtesy H. Staudinger

the same length of molecule because of the presence of the glucose ring<sup>176</sup> (See Table 8.) By preparing analogous compounds having ring members attached to a long and extended chain, the increment in viscosity due to the presence of the ring may be taken into account.

Polyethylene oxide exists in two forms as determined by viscosity measurements.<sup>177</sup> The lower polymers possess the ordinary "zig-zag" configuration.

<sup>a</sup> H. Staudinger, "Hochmolekularen Organischen Verbindungen," p 104

The viscosity values for very high-molecular-weight molecules has been questioned. In the study of the polyoxydecanoic acids,<sup>179</sup> it was found that the molecular weights of the polymers could be obtained by titration up to values of 25,000. These values were checked by ultracentrifuge determinations and were found to be in agreement. Comparison with the viscosity determinations, however, showed that the viscosity method gave reliable values up to a molecular weight of 16,000 but from this point up to a molecular weight of 25,000 increasing errors appear.<sup>180</sup>

Staudinger<sup>181</sup> has replied that the non-agreement really occurs in the lower members of the series as might be anticipated for a highly co-ordinated molecule, whereas much better values are obtained for the range 16,000-25,000. The specific viscosity of a single carbon in the lowest polymer (mol. wt. 780) is  $3.1 \times 10^{-3}$ ; the value falls to  $1.4 \times 10^{-3}$  for a molecular weight of 9300 and remains constant up to the molecular weight of 25,000.

In the relationship

$$\frac{\eta_{sp}}{c} = Km M,$$

the following equation is also valid

$$\frac{\eta_{sp}}{c} = K_1 L$$

where  $L$  stands for the length of the molecule. According to the Einstein law

<sup>178</sup> E. Sauter, *Z. physik. Chem.*, 1933, 21, 161, 186; *Chem. Abs.*, 1933, 27, 3867 Cf. Chapter 50.

Sakurada and S. Lee, *Kolloid-Z.*, 1932, 61, 80; *Chem. Abs.*, 1933, 27, 837. I. Sakurada, *Ber.*, 1934, 67, 1045. R. Obogi and E. Broda (*Kolloid-Z.*, 1934, 69, 172; *Chem. Abs.*, 1935, 29, 1696) compared viscosity and osmotic pressure determinations over a series of concentrations and found that a parallel existed between the viscosity and the molecular weight determinations from osmotic pressure. These investigators consider that Staudinger's relation may be used as an approximate empirical relation up to molecular weights of about 60,000.

the viscosity of the solution is dependent only on the total volume,  $\varphi$ , of the dissolved phase

$$\eta_{sp} = K \varphi$$

For long thin molecules, on the other hand, with the viscosity increasing with the length of the chain, the volume of a chain molecule, effective with respect to viscosity, is not equal to the volume proper but increases with chain length. The effective volume (expressed by Staudinger as a flat cylinder generated by the rotation of a single molecule) can be written as

$$\varphi = \left(\frac{L}{2}\right)^2 \cdot \pi \cdot d$$

where  $d$  is the diameter of the chain. If two chains align themselves to form a single chain, the total effective volume changes from

$$\varphi = N \left(\frac{L}{2}\right)^2 \cdot \pi \cdot d$$

to

$$\varphi = \frac{N}{2} \left(\frac{L}{2}\right)^2 \cdot \pi \cdot d$$

If, on the other hand, the number of chain molecules is halved due to the formation of chains twice the length of one chain, the effective volume changes from

$$\varphi = \frac{N}{2} \left(\frac{2L}{2}\right)^2 \cdot \pi \cdot d$$

to

$$\varphi = 2N \left(\frac{L}{2}\right)^2 \cdot \pi \cdot d$$

The effective volumes, therefore, of chain molecules of different length increase proportionately to the *square* of the length of the chain, that is, to the *square* of the molecular weight.

Because of the large effective volume of the long chain molecules, even their dilute solutions are not ordinary. As the concentration increases, the total effective volume quickly outstrips the available volume. A gel solution can therefore be considered as one where the effective volume of the long molecules is greater than the actual volume of the solution. Such a gel condition can not be obtained with substances of low molecular weight inasmuch as the molecules extend equally in all dimensions, consequently the sphere of activity of a molecule is almost identical with its own volume.

#### THE APPLICATION OF X-RAY METHODS TO MACROPOLYMERS

Mention has already been made concerning the use of x-rays in the elucidation of the structure of certain natural products, the linear polymers. The field of amorphous products is one of the most recent to which x-ray analysis has been applied.<sup>122</sup> Much pioneer work, however, needs to be done although enough has

<sup>122</sup> In addition to the references already cited, the following summaries have appeared: G. L. Clark, "Applied X-Rays," McGraw-Hill Book Co., Inc., New York, *Ind. Eng. Chem.*, 1929, 23, 128. S. E. Sheppard, *Ind. Eng. Chem.*, 1931, 25, 781. See also G. Natta, *Giorn. chim. ind. applicata*, 1934, 16, 285; *Chem. Abs.*, 1935, 29, 130. H. Staudinger, "Hochmolekularen organischen Verbindungen," J. Springer, Berlin, 1932. R. Houwink, "Physikalische Eigenschaften und Feinbau Natur- und Kunstharzen," Akad. Verlagsges. m. b. H., Leipzig, 1934. K. H. Meyer and H. Mark, "Der Aufbau der hochpolymeren organischen Naturstoffe," Akad. Verlagsges. m. b. H., Leipzig, 1930. For other discussions on x-rays cf. E. Schmid and W. Boas, "Kristallplastizität," J. Springer, Berlin, 1935. A. H. Compton and S. K. Allison, "X-Rays in Theory and Experiment," D. Van Nostrand Co., Inc., New York, 1935.

been accomplished to indicate that x-ray analysis should prove to be a most useful tool.

The first application of x-ray methods was to that of crystal structure. Acting on the suggestion of Laue,<sup>183</sup> Friedrich and Knipping<sup>184</sup> found that a crystal acted as a 3-dimensional optical grating for x-rays. Shortly afterwards the Braggs<sup>185</sup> modified the Laue method to make possible not only the direct determination of the actual arrangement in the crystal but also provide a means of determining the wave length of x-rays.

In the Laue method the rays are passed through the crystal and the image registered on the photographic plate. The image produced is one of a symmetrically arranged group of spots. If, while the photograph is being taken, the crystal is rotated perpendicular to the x-ray beam, all of the spots become arranged on a series of curves, one parallel and the other perpendicular to the axis of rotation.

Fig. 11  
Derivation of Bragg's Law

The Braggs were able to show that the diffraction by the crystal could be treated more easily as reflections from the successive planes of ions (or atoms) rather than a 3-dimensional grating. The treatment is analogous to the refraction of visible light from a stack of very thin plates of glass. The problem is very much simplified, however, if the reflected beam is considered as equal to the angle of incidence (See Fig. 11). Under these conditions, an expression can be developed

$$n\lambda = 2d \sin \theta$$

where  $\lambda$  is the wave length of the light,  $d$  is the distance between the planes,  $\theta$  is the angle of refraction (or the "glancing angle of reflection") and  $n$  is an integer, usually small, called the order of diffraction.

Inasmuch as the crystal has several "faces" or planes (see Fig. 12), the analysis of the crystal structure by the Bragg method involves the determination of the relative spacing of the planes perpendicular to the principal directions of the crystal. Either the naturally occurring planes in the crystal may be used or the planes may be ground on the crystal, either procedure, however, involving the use of a fairly large well-developed crystal. The discovery by Hull<sup>186</sup> and by Debye and Scherrer<sup>187</sup> that the minute crystals present in a crystalline powder could reflect x-rays, opened new fields for x-ray research. It will be noted that under these conditions (see Fig. 13) the photograph is characterized by a series of rings. A crystal rotating about a fixed axis gives rise to a set of single spots. When the crystal is in the powdered condition, each spot will be repeated many times with the resultant effect that rings are produced.

No discussion of crystallographic work will be given here,<sup>188</sup> save for the crystal structure of diamond and graphite. (See Fig. 14.) The staggered carbon layers in diamond account for its extreme hardness, while the flat layers of graphite can

*Courtesy G. L. Clark*

FIG 12—Typical Sets of Parallel Planes in a Cubic Lattice.

easily be used to explain the latter's fine lubricating properties, since the bonds from carbon layer to carbon layer may be ruptured easily. Many such examples

FIG 13.

of the correlation of physical properties and crystal structure are known and undoubtedly the microscopic properties of a solid are influenced to an enormous extent by the properties of the fundamental crystallographic unit.

<sup>188</sup> For further details, bibliography and discussion, see R. W. G. Wyckoff, *J. Franklin Inst.*, 1923, 195, 183, 349, 531 and "The Structure of Crystals," Chem. Catalog Co., N. Y., 1924.

In the study of liquids and amorphous solids such as glasses, resins, colloids and various natural and synthetic organic compounds, the angles of diffraction are not sharp and well defined as in the truly crystalline substances but are quite broad. The x-ray patterns show halos instead of sharp rings or spots. A perfectly amorphous substance should yield a diffraction pattern consisting essentially

*Courtesy Central Scientific Co*

FIG. 14—The Structures of Diamond and Graphite as Deduced by X-Ray Diffraction Methods

of only a general fogging with no signs of halos or preferred scattering at any angle. Any kind of an arrangement of the ultimate units in an imperfectly amorphous material, of the most rudimentary variety, would result in the registration of a broad halo upon the photographic plate. A single broad diffraction halo indicates, at least, an elementary tendency toward organization. Liquids

FIG. 15.  
A Typical X-Ray Diffraction Pattern of a Liquid

*Courtesy S. E. Sheppard*

(see Fig. 15) and gases are known to produce such halos so that even here we are not dealing with perfectly amorphous substances. It seems likely that these halos, simple as they are, measure some fundamental periodicity associated with the pseudo-amorphous solid.

A measurement of the diameter of the halo together with its breadth and intensity with respect to the general background yields information which, when

properly interpreted, is of considerable significance. Especially is this true, in the case where it is desired to show that two substances, although of identical chemical composition and prepared by similar methods, are fundamentally different. This difference may arise in a slight shift in the halo, a change in its breadth or an alteration of the intensity. If the substances are different, perfectly matched x-ray patterns do not occur.

It can be seen, therefore, that although the theoretical nature of the origin of the halos of these pseudo-amorphous substances is at best imperfectly understood, information can still be obtained. When this information is properly correlated with physical and chemical data, conclusions of considerable significance may be expected.

**Experimental Procedure.** In Figure 16 is a diagrammatic sketch of the general experimental set-up. The figure shows a Muller-Femstruktur copper x-ray tube hav-

ing an operating voltage of about 30,000 volts and 25 milliamperes. The x-ray beam of 1.54 Ångstrom units ( $1.54 \times 10^{-8}$  cm.) wave length is defined by two .025-inch lead pinholes. The distance from the plate to the specimen under examination is 300 cm. Samples are usually adjusted to 1 mm. thickness. The mounting is fixed and the beam of x-rays transmitted perpendicularly. In general, to obtain accurate results care is taken with the time of exposure of films, control of voltage and amperage of the x-ray tube and finally with the development of the negative. The developed negatives are best compared by obtaining intensity curves which allow breadth of the rings, the intensity and the distance from the source to be read directly.

Beal, Anderson and Long<sup>109</sup> studied the resins obtained from the polymerization of cumarone and indene<sup>100</sup> by x-ray methods. (See Figs. 18 and 19) The resins made by polymerizing a coal tar naphtha distillate were not amorphous but gave well-defined rings which indicated fundamental spacings within the resin molecules. (See Table 9.)

FIG. 17.—X-ray Diffraction Equipment at the University of Illinois.

several factors revealed by x-ray data. (1) The 5.3 Å spacing is evidently caused by the thickness of the individual cumarone and indene molecules, and since this spacing persists in the highly polymerized resin, the molecules must be so combined that their thickness can still give rise to an intensity maximum. (2) In the polymerization process, a new arrangement of the molecules giving rise to a spacing of 9.1 Å is formed; and (3) in the liquid resin, which is a very low polymer, the

spacing due to the thickness of the molecule has disappeared." They further suggested that the molecules first polymerize into groups which possess the thickness of the single molecule. The thickness spacing is lost at this stage due to random arrangement. As polymerization proceeds, the molecules align themselves into layers separated by a distance equal to the thickness of the individual

FIG. 18.  
Indene, Copper Radiation.

molecule, thus bringing about the reappearance of the 5.3 Å spacing. That it returns unchanged is taken as evidence that the layering is due to forces other than primary chemical valencies. The precise origin of the outer spacing is not

FIG. 19.  
Indene, Copper Radiation

clear, but the 2.2 Å ring is found to appear in many natural resins. Possibly the reappearance of the 5.3 Å ring is due to the production in the later stages of polymerization of a new repeating unit, not identical with that giving rise to the first 5.3 Å spacing.

Trillat<sup>191</sup> and others, including the author,<sup>192</sup> have investigated the condensation products of phenols with formaldehyde with respect to the x-ray patterns. In Table 10 are given the results which are very interesting when analyzed in the light of polymerization phenomena, fusibility and solubility and bear out the current theories concerning the structure of the phenol-formaldehyde type resin.<sup>193</sup>

<sup>b</sup> The numbers refer to illustrations

In the study of synthetic resins and compounds of the type which are susceptible to polymerization, the determination of the intensity of the lines is of the utmost importance. From the above table it will be seen that in proceeding from the phenol to the xylenol resin, the tendency is to form larger spacings. This tendency, especially for the spacings labeled  $d^1$  and  $d^2$ , is probably increased by the side chains on the aromatic nucleus. Thus one would expect to find that a greater increase in  $d^1$  and possibly  $d^2$  will be found in an o-butylphenol-formaldehyde resin, less of the same tendency in a p-butylphenol resin. In resins 20, 21 and 22 it will be seen that as polymerization proceeds the intensity of the rings becomes less and less. An examination of the intensity curves for these resins reveals that the curves are becoming less undulating, that is, the difference between trough and crest is becoming less and less. The lessening of intensity of the outer halo shows greater spatial distances, indicating a greater degree of polymerization. The resin marked 23 is a fusible xylenol resin; its x-ray properties approximate that of the potentially reactive soft resin 21.

In Table 11 and Figures 24, 25 and 26 are given three different stages of the same phenol-formaldehyde resin: 24 is the phenol-formaldehyde resin made by refluxing 1 mol phenol with 1.5 mols of formaldehyde in the presence of sodium carbonate, and dried *in vacuo*; 25 is the same resin cured under 3000 pounds per square inch at 120-130°C.; while 26 is the same resin compressed at 3000 pounds per square inch at 70°C., then removed from the press and heated in an oven at 70°C. with the temperature gradually rising to 140°C. until cured.

polymerization. The maximum shifts to a somewhat larger value as polymerization increases, as does the intensity. In the primary resin the single band is well defined and narrow but polymerization causes a broadening and a smoothing which indicates random clustering of primary aggregates with less approach to orientation.

tendency toward the 3-dimensional polymer. Moreover, the maximum near 8 mm. from the central spot becomes more pronounced as the reaction becomes more complete. This increase in definition of the maximum is explained by an increased tendency for definite orientation and a closer approach to crystallinity. This does not mean crystallinity in the ordinary sense of the word, but an alignment of the molecules of the resin to give the semblance of crystallinity. In other words, the fully cured resin assumes the properties of a macro-pseudo-crystallite.

<sup>106</sup> See Chapter 42.

In casting resins one would expect to observe a similar phenomenon. In this instance, as the resin slowly hardens, orientation to a crystallite state can take place more easily.

A difference may be pointed out between the methods of polymerization of phenolic resins and that of the phthalic glycerides. In phenolic resin the contrast between the maximum and minimum becomes less distinct and the intensity curves have a tendency to become smooth; in phthalic glyceride, however, these curves become more jagged. Polymerization, therefore, is taking place with orientation

and hence a nearer approach to the crystalline state. The polymerization of the phenolic resin, on the other hand, takes place through a clustering of primary aggregates with no approach but rather a recession from a crystalline state.

The influence of rosin in the resin molecule may be seen in Figures 34 and 35. The first is a rosin modified phthalic glyceride while the second is a maleic anhydride adduct of rosin.<sup>196</sup> One might say the two substances were identical, so closely do their patterns match. There are some slight differences, only enough to show there are two different substances being examined. Beal, Anderson and Long<sup>197</sup> have studied the products obtained by modifying phenolic resins and phthalic glyceride with ester gum. (See Table 14.)

poration of synthetic materials, has apparently little effect upon the fundamental molecule present in rosin. The fact that even by modifying rosin to such an extent as reacting it with maleic anhydride does not change its character is especially significant. X-Ray methods would seem to offer a positive method of identifying this natural substance in all of its forms in commerce.

Large atoms, naturally having more mass, give more intense lines in the x-ray diffraction patterns and superficially may be detected more easily. In the following series sulphur is the large atom. Such large atoms are predominant throughout a series. In the following table and Figures 36, 37 and 38, 36 is the

reaction product of glycerol dichlorhydrin-sodium polysulphide; 37 of ethylene dichloride-sodium polysulphide;<sup>196</sup> and 38 of phenol-sulphur chloride.<sup>196</sup>

38) Phenol-Sulphur Chloride Resin	4 8	9 32	16	22

These three substances resemble each other closely as regards their x-ray patterns. Proceeding from glycerol-sulphur to phenol-sulphur and to ethylene-sulphur resin, it is apparent from the intensity curves that the spacing  $d^1$  becomes weaker and weaker until it is finally non-existent. The phenomenon may be due to a greater polymerization existing in the substance, but the explanation is doubtful. No concept at present can be offered for this interesting fact.

FIG 39—X-Ray Pattern of Unstretched Chloroprene.<sup>a</sup>

<sup>a</sup> Courtesy W. H. Carothers. Photograph taken by A. W. Kenney

The behavior of rubber both in the stretched and unstretched states has already been considered. According to Mark<sup>200</sup> all of the synthetic polymerized products from isoprene and other unsaturated hydrocarbons yield, even when stretched, a diffraction pattern analogous to that of a liquid. Duprene or polymerized chloroprene<sup>201</sup> is the first synthetic rubber-like material to give a characteristic x-ray pattern on stretching.<sup>202</sup> (See Figs. 39, 40 and 41.)

Carothers and Hill<sup>203</sup> have made a study of artificial fibers produced from hexadecamethylene dicarboxylic acid and trimethylene glycol. Filaments are produced from the molten ester by touching it with a stirring rod and then drawing the rod away, or by extruding a chloroform solution. If sufficient tension is applied during the spinning, lustrous threads of improved mechanical properties result; otherwise the thread is opaque and lacks luster. The opaque thread shows an x-ray diagram with several fairly well defined rings; with the lustrous material a series of spots is observed, which, while not so complex as in the case of ramie, is of the

same type. These results indicate the orientation of the crystal units in a lustrous fiber. A similar oriented fiber was obtained with ethylene sebacate, as well as with mixed polyesters and polyamides of the type derived from  $\epsilon$ -aminocaproic acid.

The polyoxymethylenes,<sup>204</sup> formed by the polymerization of formaldehyde, offer a very interesting example of the application of x-rays. The chemistry of these

FIG. 40.  
X-Ray Diffraction Pattern of Stretched Chloroprene.<sup>a</sup>

substances has been studied exhaustively by Staudinger and his co-workers.<sup>205</sup> X-Ray examination of the lower crystalline polyoxymethylenes indicates that they are linear polymers comparable to the paraffins, i.e., a zig-zag chain structure. (See Fig. 42.)

The end groups of the chain-like molecules do not show definite characteristic features in the x-ray photograph. It is only the unit in the chain, and the distances of the chains from one another which are significant. Thus polyoxymethy-

FIG. 41

lene hydrate and polyoxymethylene dimethyl ether yield x-ray patterns which are almost identical.

The type of arrangement shown above is obtained only with relatively short polymers. In the case of polymers of greater molecular weight, which are as a rule insoluble, there is no definite intermolecular distance in the arrangement. The molecules in general are still oriented in parallel bunches, though they lie end to end without any definite arrangement.

<sup>204</sup> See Chapter 23.

<sup>205</sup> H. Staudinger, "Hochmolekularen organischen Verbindungen," 1932, 224, *et seq.*

It is characteristic of x-ray diffraction patterns obtained from very small particles that the lines of the photograph become broad and hazy as the particle size is reduced<sup>200</sup>. The case of colloidal gold is illustrative. Gold normally gives sharp lines and the lattice is cubic. When the metal is in the colloidal state, however, with a particle size corresponding to only about 20 atoms, diffuse lines are observed, though the cubic symmetry is retained. The same feature is observed

FIG. 42—The Probable Arrangement of Octa-oxyethylene Diacetate Molecules.

during the transformation from the amorphous to the crystalline state. The aggregates formed in the early stages of crystallization are very small, and hazy diffraction bands are produced. As the crystals develop the bands sharpen into the usual lines. This is true of the polyoxymethylene hydrate gel. Immediately after preparation there is a nearly complete random arrangement of the molecules and the rings are very diffuse. The appearance after 2 days is somewhat different. There is a definite pulling together of the molecules into ordered groups and as a result the diffraction lines become much sharper.

## Chapter 5

### Cumarone and Indene

Cumarone, indene and their homologues are the parent substances for the production of the so-called cumarone resins. Their occurrence and general reactions are summarized in this chapter.

Resins are produced from cumarone and indene by direct homo-polymerization in the presence of a catalyst such as sulphuric acid. As indicated by its structural formula, indene is a hydrocarbon possessing both olefinic and aromatic properties. In its high chemical reactivity and tendency to polymerize, indene is similar to styrene<sup>1</sup> and cyclopentadiene.<sup>2</sup> Cumarone is the oxygen analogue of indene.

The structural relationships can be seen as follows:

All of the compounds are, in effect, substituted ethylene derivatives<sup>3</sup>

In practice, separation of pure indene and cumarone is both difficult and expensive; hence, fractions of solvent naphtha (coal-tar distillate) rich in cumarone and indene are used as raw materials in resin manufacture, since polymerization readily occurs despite dilution by other compounds. For various reasons (one of which was the presence of other unsaturated, polymerizable substances in solvent naphtha) the first attempts at commercial manufacture of resins yielded dark sticky products of limited application. Methods of purification of the raw material and the technic of resinification have been so developed that light-colored, hard resins of manifold uses are now easily made. The present commercial cumarone resins are clean, nearly odorless products. They differ markedly from the offensive tars and acid sludges (obtained in the usual course of acid-refining of coal-tar naphtha) which, though containing resins, also include so many undesirable substances as to be practically useless.

#### CUMARONE

Cumarone is a water-white, oily liquid of peculiar odor, boiling at 172°C. and having a specific gravity of 1.096 at 15°. It is insoluble in water and volatile with

<sup>1</sup> See Chapter 11

<sup>2</sup> See Chapter 9

<sup>3</sup> See Chapter 51 for the effect of different substituent groups on the properties of compounds possessing the ethylene or vinyl grouping.

steam and is present in the fraction of coal-tar naphtha boiling between 168-175°, which is the source of cumarone for resin manufacture.

Kraemer and Spilker<sup>4</sup> isolated cumarone from a coal-tar fraction (boiling between 168° and 175°C) which had been treated with caustic alkalis and with acid. They brominated 1 kilogram of this material by the gradual addition of 450 grams of bromine while maintaining the temperature below 0°C., and obtained 80 grams of cumarone dibromide, which crystallized in prisms melting at 88-89°C. By prolonged boiling with alcoholic potash under reflux, the dibromide was converted to bromocumarone (m.p., 39°). From a solution of bromocumarone in 70 per cent alcohol, cumarone was regenerated by reduction with sodium amalgam.

Later, these same investigators<sup>5</sup> obtained cumarone by resinifying a crude coal-tar naphtha (b.p. 155-185°C) with sulphuric acid, destructively distilling the resins formed, and converting the cumarone in the 168-172° fraction into the picrate. They stated that this method of separating cumarone from hydrindene (indane), which occurs in the same fraction, is easier than separating the former directly from crude-tar naphtha. The method has been criticized by Burda and Sukacheva,<sup>6</sup> who, by using it, secured only 0.11 per cent yield of cumarone from a solvent naphtha boiling between 140° and 200°C.<sup>7</sup>

**Chemical Properties of Cumarone.** The name cumarone is unfortunate in that it suggests, quite erroneously, this substance is a ketone, whereas it is an unsaturated cyclic oxide. Cumarone has been synthesized by a number of methods, which are only of purely scientific interest. It was prepared by Fittig<sup>8</sup> by distilling cumarilic acid with lime, the reaction being represented thus:

Rössing<sup>9</sup> obtained cumarone by boiling o-aldehydephenoxyacetic acid

with anhydrous sodium acetate and acetic anhydride. Another procedure is the treatment of phenoxyacetaldehyde with glacial acetic acid and zinc chloride.<sup>10</sup> One synthesis of cumarone depends upon the elimination of hydrogen chloride from o-hydroxy-β-chlorostyrene by alkalis.<sup>11</sup>

<sup>4</sup> G. Kraemer and A. Spilker, *Ber.*, 1890, 23, 78.

<sup>5</sup> G. Kraemer and A. Spilker, *Ber.*, 1900, 33, 2257; *J. C. S.*, 1900, 78 (1), 656.

<sup>6</sup> N. I. Burda and U. D. Sukacheva, *Ukrain. Khim. Zhur.*, 1931, 6, (Sci.), 169; *Chem. Abs.*, 1932, 26, 2192.

<sup>7</sup> This criticism must be considered carefully because of the uncertainty of the origin of the naphtha used by Burda and Sukacheva. If it was a commercial product some polymerization may have occurred previously and it is even possible that the normal traces of other hydrocarbons had been increased by the addition of residual fractions from other distillations.

<sup>8</sup> R. Fittig and G. Ebert, *Ann.*, 1883, 216, 168; *Ber.*, 1883, 16, 413; *Ann.*, 1884, 226, 354.

<sup>9</sup> A. Rössing, *Ber.*, 1884, 17, 3000.

<sup>10</sup> R. Stoerner, *Ber.*, 1897, 30, 1703.

<sup>11</sup> G. Komppa, *Ber.*, 1893, 26, 2969.

One of the characteristics of cumarone is the stability of its oxide ring system. This is not affected by potassium cyanide, by hot hydrochloric acid or by ammonia at 280°C. Cumarone is not decomposed by boiling aqueous or alcoholic potash, although concentrated alcoholic potash at 200° hydrolyzes it with rupture of the oxide ring.

The unsaturated character of cumarone is shown by its numerous addition reactions and by its power of additive polymerization. With bromine in the cold it readily forms a dibromide (m.p., 88-89°C.).<sup>12</sup> On hydrogenation, either catalytically or by sodium and boiling alcohol, the corresponding dihydride, dihydrocumarone,

results,<sup>13</sup> together with o-ethylphenol as a by-product. Cumarone combines with nitrous acid to yield nitrosites<sup>14</sup> and with hypochlorous acid to give a mixture of isomeric chlorohydrins. From the latter Boes<sup>15</sup> isolated a chlorohydrin (m.p. 123°C.) convertible by potassium hydroxide into cumarone glycol (m.p. 151°). Strong inorganic acids, including sulphuric, phosphoric, hydrobromic and hydriodic acids, polymerize cumarone, the products being of a resinous nature. By careful nitration with concentrated nitric acid, Stoermer and Richter<sup>16</sup> obtained a mixture of two isomeric nitrocumarones, an oxidation product and resinous substances. Oxidizing agents, such as bleaching powder and potassium permanganate react violently, the latter causing the formation of a resin.

Cumarone is distinguished by its stability at high temperatures. Kraemer and Spilker<sup>17</sup> found that 94 per cent of the compound remained unchanged after passage through a red-hot tube. The stability of cumarone and its homologues at high temperatures permits their formation in a number of pyrolytic reactions, and explains their occurrence among the products obtained by cracking higher-boiling phenols of primary coal-tar.<sup>18</sup> Cumarone results from the pyrolysis of cumarin at 860°C. and atmospheric pressure<sup>19</sup> and polymerized methyleumarones have been produced by the pyrolysis of hexahydrodiphenylene oxide.<sup>20</sup>

Cumarone forms a characteristic picrate (m.p. 102-103°C.),<sup>21</sup> and yellow, crystalline, unstable double compounds with 1,3,5-trinitrobenzene (m.p. of equimolecular addition product, 103.5-104°).<sup>22</sup>

**Polymerization of Cumarone.** The polymerization of cumarone has been studied less systematically than that of indene, but indications are that the mechanisms are similar. Much of the work, however, is rendered somewhat uncertain by the fact that investigators have used impure cumarone as the starting material.

<sup>21</sup> G. Kraemer and A. Spilker, *Ber.*, 1890, 23, 3276. Cf. British Patent 1422, 1890, to Chem. Fabrik. A.-G.; *J. S. C. I.*, 1890, 9, 546. German Patent 53,792, 1890; *Chem. Zentr.*, 1891, 1, 111.

<sup>22</sup> J. J. Sudborough and S. H. Beard, *J. C. S.*, 1911, 99, 209, 215.

Kraemer and Spilker<sup>23</sup> found that when a solution of cumarone in benzene is shaken with sulphuric acid the greater part of it is converted into a resin soluble in benzene and the remainder separates as a brown insoluble powder. If 80 per cent sulphuric acid is used as polymerizing agent the soluble resin is formed almost exclusively. The yield of the insoluble resin increases with the concentration of the acid; with 95 per cent sulphuric acid, the insoluble resin is formed quantitatively. A soluble resin melting at 107-108°C. and having a specific gravity of 1.25 had a molecular weight corresponding to a tetramer of cumarone,  $(C_8H_6O)_4$ .<sup>24</sup> When heated at 300-350°, this resin furnished a distillate consisting mainly of cumarone together with some phenol, ethylbenzene, and small quantities of o-ethylphenol, toluene, and dihydrocumarone.

Insoluble resins formed by the action of concentrated sulphuric acid were found by Kraemer and Spilker<sup>25</sup> to contain combined sulphur. On destruc-

FIG. 43

X-Ray Diffraction Pattern of a Cumarone Resin (Cumar) Copper Radiation.

Courtesy H. V. Anderson

tive distillation these substances yielded sulphur, sulphur dioxide, hydrogen sulphide and practically the same products as those obtained from the soluble resins. According to Kraemer and Spilker, the polymerization of cumarone proceeds with little rise in temperature but that of indene is attended with a considerable evolution of heat.

Besides sulphuric acid, a number of other agents polymerize cumarone to substances of a resinous nature. Heusler<sup>26</sup> noted that anhydrous aluminum chloride converted cumarone into a soluble resin. Stein<sup>27</sup> observed that aluminum chloride, phosphorus oxychloride and stannic chloride (particularly the latter) cause resinification. On the other hand, silicon tetrachloride, zinc chloride, hydrogen chloride, sulphur monochloride, and potassium hydrogen sulphate exert little or no action. Cumarone, exposed to air, undergoes autoxidation and subsequent polymerization.

From the meager data available it appears that the resinification of cumarone by catalysts is a purely additive polymerization, although an excess of concentrated sulphuric acid effects some sulphonation.

<sup>23</sup> G. Kraemer and A. Spilker, *Ber.*, 1900, 33, 2257; *JCS*, 1900, 78 (1), 656.

<sup>24</sup> R. Stoermer (*Ann.*, 1900, 312, 237) obtained, during the preparation of cumarone by the dehydration of phenoxyacetaldehyde, a polymer of cumarone, having a molecular weight corresponding to  $(C_8H_6O)_4$ , a yellow-brown powder melting at 80-100°C. This polymer was very soluble in ether, benzene and chloroform but less soluble in alcohol.

<sup>25</sup> G. Kraemer and A. Spilker, *Ber.*, 1901, 34, 1887.

<sup>26</sup> F. Heusler, *Z. angew. Chem.*, 1896, 9, 318.

<sup>27</sup> E. Stein, *Z. angew. Chem.*, 1919, 32, 246; *Chem. Abs.*, 1920, 14, 641.

The name "paracumarone"<sup>228</sup> has been applied to the benzene-soluble resins obtained by the controlled polymerization of cumarone. This material, which is of variable melting point, is soluble in many of the ordinary organic solvents (with the exception of alcohol) and is stable towards alkalis and most acids.

**Homologues of Cumarone.** Isomeric methylcumarones were found by Stoermer and Boes<sup>229</sup> in the fraction of coal-tar distillate boiling between 185° and 200°C. By treating a coal-tar fraction (boiling range 185-195°C.) with sulphuric acid they prepared polymers of methylcumarone which decomposed, on heating, into hydrindene and methylcumarone, together with the corresponding cresols.

Stoermer and Boes also isolated dimethylcumarones from the fraction of tar oils boiling between 215° and 225°. These compounds were not resinified by concentrated sulphuric acid.<sup>230</sup>

### INDENE

**Occurrence of Indene.** Indene is a colorless oily liquid boiling at 182°C., solidifying at -2° and possessing a specific gravity of 1.0002 at 15°C.<sup>231</sup> It is an important constituent of certain fractions of tars and naphthas obtained in the

high-temperature carbonization of coal and similar bituminous materials. From 10 kilograms of a coal-tar naphtha, boiling between 176° and 180°C., Kraemer and Spilker<sup>232</sup> obtained 3 kilograms of crude indene. Weissgerber<sup>233</sup> used a 175-185° fraction of solvent naphtha as a source of pure indene. Indene is present to a much smaller extent in the so-called primary tars produced by the carbonization of bituminous substances at lower temperatures.<sup>234</sup> This is attributed to the fact that indene, like most polynuclear aromatic hydrocarbons, is essentially a product of high-temperature pyrolytic reactions.<sup>235</sup> Accordingly, indene (and other cyclic hydrocarbons) is produced during the high-temperature pyrolysis of many organic substances, notably in the thermal decomposition of acetylene-hydrogen mixtures,<sup>236</sup> and of the higher-boiling phenols of primary tar.<sup>237</sup> Pyrolysis of desulphurized (Persian) natural gas, at 850° and a pressure of 20 pounds per square inch, yielded about 5 per cent styrene and 2 per cent indene.<sup>238</sup> Two carbureted water-gas tars examined by Brown and Howard<sup>239</sup> possessed an indene content of 1.9 and 1.2 per cent, respectively, of the total volume of tar.

<sup>228</sup> Since, in all probability, a whole series of polymerized cumarones exists, these resins should be more properly designated by the term "polycumarone." The ordinary cumarone resin of commerce is frequently called paracumarone, though actually a mixture of polymerized cumarones and indenenes. The name paracumarone was applied by G. Kraemer and A. Spilker (*Ber.*, 1890, 23, 78) to the resin produced by polymerizing cumarone with sulphuric acid.

Although coal-tar naphthas serve as the principal sources of indene for technical purposes, there are indications that coal gas and carbureted water-gas are potential sources of large amounts of both indene and styrene. Indene and other reactive hydrocarbons are appreciably volatile in freshly-made gas, and are carried forward in the gas stream, later polymerizing to form gummy deposits in the gas-handling equipment. The indene content of freshly-made carbureted water-gas may exceed 100 grams per 1000 cubic feet.<sup>40</sup> A survey of the gas industry in the United States, according to Brown,<sup>41</sup> revealed that 6.5-10 million gallons of drip oil were produced annually which contained large proportions of styrene and indene. The oily condensate collecting in gas mains is also a potential source of indene and allied substances. Examination of representative samples of the oily condensate (drip oil) from carbureted water-gas mains revealed that the dried liquid contained up to 35 per cent indene and 15 per cent styrene. Fractions containing 75 per cent indene were obtainable by rough fractionation.

Indene has been prepared by a number of syntheses, none of which, however, appears to be of industrial significance.<sup>42</sup>

**Chemical Properties of Indene.** The olefinic nature of indene is indicated by numerous addition reactions. Reduction by sodium in boiling alcohol,<sup>43</sup> or by hydrogen and a nickel catalyst at 200°C.,<sup>44</sup> results in the addition of 2 hydrogen atoms to the indene molecule. Hydrindene (indane), a stable hydrocarbon, is thus obtained:

With halogens, indene readily forms the corresponding dihalides (dihalogenoindanes). Indene dibromide, prepared by bromination of indene in carbon tetrachloride solution at 0°C., is a crystalline solid<sup>45</sup> (m.p. 31.5-32.5°C.)<sup>46</sup> which is readily converted by the action of boiling water or steam into the corresponding hydroxybromide (m.p. 130.5°). This hydroxybromide, which has proved useful in the identification of indene,<sup>47</sup> possesses the structure:

Nitration of dibromoindane yields a yellow sticky resin.<sup>48</sup> Chlorination of indene

gives a liquid dichloride which can be hydrolyzed by boiling aqueous alcohol to the corresponding hydroxychloride.<sup>49</sup> Indene combines readily with hydrogen halides (except hydrogen fluoride) with the formation (in good yields) of halogenoindanes of the general formula:

(X = Cl, Br, or I)

The hydrochloride (chloroindane) may be made by saturating indene with dry hydrogen chloride at 0°. <sup>50</sup> However, the corresponding bromo- and iodoindanes, although obtainable in good yields, cannot be purified and, unless immediately used, lose hydrogen halide and form polymers of indene.<sup>51</sup> Hydrogen fluoride exerts a strong polymerizing action on indene.

Pure indene on exposure to air rapidly absorbs oxygen and is converted into a substance insoluble in alcohol and not distillable with steam.<sup>52</sup> It can be oxidized by aqueous potassium permanganate to 1,2-dihydroxyindane, and subsequently to homophthalic acid (2-carboxyphenylacetic acid).<sup>53</sup> Like other unsaturated hydrocarbons, indene yields a nitrosite with nitrous acid and forms a double compound with mercuric sulphate.

The methylene group of the five-membered ring of the indene molecule is capable of undergoing a series of characteristic reactions which markedly accentuate the similarity of indene to cyclopentadiene and differentiate it from cumarone. Thus, when indene is treated with sodamide at 110-115°C., one hydrogen atom of the reactive methylene group is displaced by sodium to yield sodium indene,<sup>54</sup> a substance which can be used in the preparation of pure indene. The reaction of sodium indene with benzyl chloride<sup>55</sup> yields benzyhindene (m.p. 33-34°). Like cyclopentadiene, indene can react with aldehydes in alkaline media, and its reaction with benzaldehyde has been proposed as a basis of a method for the estimation of indene.<sup>56</sup> Condensation of indene with ethyl oxalate in the presence of sodium ethoxide at ordinary temperatures produces, after acidification, ethyl indeneoxalate,<sup>57</sup> a crystalline orange-red substance (m.p. 85°C.) having the constitution:

These characteristic reactions of the methylene group provide methods of separating indene from cumarone.

With an aqueous solution of picric acid, indene readily yields a crystalline precipitate of indene picrate (m.p. 98°C.).<sup>58</sup> This compound, which has proved useful in the partial separation of indene from crude materials, is soluble in benzene and alcohol and may be decomposed into its constituents by steam distillation.

**Separation of Indene from Solvent Naphtha.** For the isolation of indene from complex mixtures, such as coal-tar fractions, Kraemer<sup>59</sup> used the picrate-precipitation method as follows: The fraction of crude benzol boiling at 176-182°C. is treated with sufficient picric acid to combine with all the unsaturated hydrocarbons present. The resulting crystalline precipitate, containing the picrates of naphthalene and cumarone, as well as of indene, is subjected to steam distillation. Indene picrate is decomposed and the liberated indene distils over. From 10 kilograms of crude naphtha (b.p. 176-182°), 3 kilograms of crude indene were obtained by this procedure. However, not only is the method somewhat dangerous because of the explosive nature of these picrates, but the resulting indene is far from pure.

A more practical method for the preparation of pure indene, developed by Weissgerber,<sup>60</sup> consists in converting crude indene into sodium indene, separating the unreacted material (cumarone, naphthalene, styrene) by distillation, and decomposing the sodium indene residue with water. A crude naphtha fraction boiling at 175-185°C. is first freed from phenols and bases and treated with the stoichiometric amount of metallic sodium. Ammonia is passed through the mixture, which is thoroughly stirred and maintained at 120-130° for 5-6 hours with the exclusion of moisture and air from the apparatus. If organic bases, such as pyridine or aniline, are not first removed, a temperature of 100-105° is sufficient. The product is then distilled under reduced pressure (20-30 mm.), most of the unreacted material being volatile at about 100°. The residual dark amorphous mass is easily decomposed by water, and indene in a pure condition is isolated by steam distillation. This procedure, with slight modification, has been successfully employed by other investigators.<sup>61</sup>

Sodium indene can be obtained also from coal-tar fractions by treatment with metallic sodium at temperatures above 130°C. in the absence of ammonia. Organic bases assist this reaction but do not increase the yield.<sup>62</sup>

Separation of indene from cumarone may be effected also by converting the former into compounds in which the methylene group is the point of attack (e.g., ethyl indeneoxalate). Such derivatives, however, are not easily reconverted into indene. The hydroxybromides of indene, obtained by steam distillation of the dibromide, have been employed for separating indene from styrene.<sup>63</sup>

Another method of isolating indene from tar oils is that developed by Kahl.<sup>64</sup> This consists in fractionating the crude oils and cooling to -25°C. those fractions containing 80 per cent or more of indene. At this temperature indene of a high degree of purity crystallizes and the liquid portion is removed by centrifuging. Fractions containing less than 80 per cent indene can be cooled until partial

solidification takes place, the solid portion separated, remelted, and treated as described above.

**Polymerization of Indene.** The polymerization of indene takes place under the influence of light or heat, and more readily in the presence of a variety of catalysts, to yield a series of products, the higher members of which are resins. In this respect it shows a marked similarity to styrene.<sup>65</sup> Although concentrated sulphuric acid is employed almost exclusively as the catalyst in the polymerization of cumarone and indene to yield commercial resins, other catalysts, such as tin tetrachloride, are even more efficacious. Polymerization of indene is strongly exothermic and for this reason reaction is usually effected in liquid diluents with rapid cooling and agitation. The use of high pressures (2000-12,000 atmospheres) is suggested by Bridgman and Conant.<sup>66</sup> Not only does indene homo-polymerize, but, like styrene and the vinyl esters and ethers, it can hetero-polymerize with compounds such as  $\alpha$ ,  $\beta$ -dicarboxylic acids, or their anhydrides (e.g., maleic anhydride). The products thus obtained are used as dispersing, emulsifying and finishing agents for textiles.<sup>67</sup>

**Polymerization of Indene by Heat.** Indene undergoes little change when heated at 115-118°C. in the dark in an atmosphere of nitrogen, but after 96 hours at 190-200°C., it is transformed into a colophony-like mass which consists mainly of a mixture of polyindenes, including  $(C_9H_8)_8$  and  $(C_9H_8)_{12}$ , according to Stobbe and Färber.<sup>68</sup> By heating indene in a sealed tube at 180-200°C., for 100 hours, Stobbe and Zschoch<sup>69</sup> obtained a yellow, benzene-soluble resinous mass. A yellow amorphous powder having a molecular weight corresponding to a tetraindene,  $(C_9H_8)_4$ , was obtained by Bruson<sup>70</sup> by heating indene in a sealed tube at 260° for 25 hours. This tetraindene, which could not be crystallized, melted indefinitely at 100-110°.

Brown<sup>71</sup> found that, at 300-500°C., indene vaporized in nitrogen polymerized rapidly but when oxygen was present it underwent rapid oxidation. Whitby and Katz<sup>72</sup> showed that a series of polyindenes is produced during thermopolymerization of indene in sealed tubes. At a given temperature the molecular weight of the product was found to rise as the proportion of indene transformed increased, but the ultimate molecular size attained (when polymerization was substantially complete) was lower at higher temperatures. Thus, after 21 days at 200°C., when 96 per cent of the indene had polymerized, the molecular weight was 676, but at 178°C. after 30 days, 82 per cent of the indene had polymerized to a product with an average molecular weight of 886. Fractional precipitation of the materials from ether solution by the addition of alcohol yielded a series of polymers having melting points proportional to their molecular weights. Comparison of these thermopolymers with products obtained by the use of catalysts, such as sulphuric acid, showed that the polymers of indene, no matter by which of the known methods they are produced, form a regular and unbroken series. Another fact brought out by Whitby and Katz is that all the polyindenes show the same degree of unsaturation, namely, that represented by the addition of 2 atoms of bromine per molecule. Hence these investigators concluded that all the polyindene molecules, no matter what their size, contain 1 double bond.

<sup>65</sup> However, the polyindenes of highest molecular weight are relatively simple molecules when compared with the gigantic macromolecules formed in the polymerization of styrene. See Chapter 11

**Photopolymerization of Indene.** Transformation of indene to resins in ultraviolet light was noted by Guntz and Minguin.<sup>75</sup> According to Stobbe and Färber,<sup>74</sup> photopolymerization of pure indene in an atmosphere of nitrogen at 20°C. follows a normal, non-autocatalytic course, which is preceded by an induction period. Exposure to sunlight for a year yielded small quantities of resinous polymers,  $(C_9H_8)_8$  and  $(C_9H_8)_{10}$ . The formation of these polymers is accelerated by the presence of a trace of air.

**Catalytic Polymerization of Indene.** Sulphuric acid exerts a strong polymerizing action on indene (or its solutions), the degree of polymerization depending upon the concentration of the acid. Earlier workers in this field failed to realize the cumulative nature of the reaction and attempted to characterize as chemical individuals the complex mixture of products thus formed. Kraemer and Spilker<sup>76</sup> obtained a resinous polymer of high molecular weight (m.p. 210°C.) by treating a 20 per cent solution of indene in benzene with 15–20 per cent of concentrated sulphuric acid. This resin, to which the name paraindene was assigned, was later found to be heterogeneous and to have a variable molecular weight and melting point. Marcusson<sup>75</sup> made resins of various characteristics by polymerizing indene in benzene solution with different concentrations of sulphuric acid. By using concentrated sulphuric acid, a polymer was formed which melted at 210° and was insoluble in ether. On the other hand, diluted acid or smaller amounts of concentrated acid resulted in a mixture of products, one melting at 165°C., soluble in ether but insoluble in ether-alcohol, and another melting at 100°C. and soluble in ether-alcohol. Weger<sup>77</sup> made what he considered to be a tetramer of indene (to which he also assigned the name paraindene) by shaking a benzene solution of indene with a small proportion of concentrated sulphuric acid. By treating indene with concentrated sulphuric acid in the cold, Bruson<sup>78</sup> prepared a white amorphous product melting at 212–214°C. and having an apparent molecular weight corresponding to  $(C_9H_8)_{11}$  or  $(C_9H_8)_{12}$ . This material was similar to the paraindene of Kraemer and Spilker. The influence of various concentrations of sulphuric acid on the polymerization of indene was studied by Stobbe and Färber.<sup>79</sup> Dilute sulphuric acid (as well as other dilute mineral acids) polymerizes indene almost exclusively to the dimer. With aqueous sulphuric acid of 60 per cent strength and higher, diindene is formed as well as higher polymers. By treating undiluted indene with concentrated sulphuric acid in the cold, Stobbe and Färber obtained polymers with molecular weights lying between values required for  $(C_9H_8)_{10}$  and  $(C_9H_8)_{20}$ . These substances, which were white, amorphous, odorless powders having melting points in the range of 220–280°C., were called metaindene. The metaindene

of Stobbe and Färber consists of a mixture of indene polymers of molecular weights somewhat higher than those of the so-called paraindene of Kraemer and Spilker.

Besides sulphuric acid, a number of other mineral and organic acids polymerize indene to varying degrees. Anhydrous hydrogen fluoride is a strong polymerizing agent and converts indene to a resin. As previously mentioned, other hydrogen halides combine additively with indene but the resulting bromo- and iodoindanes are unstable and tend to form resins with elimination of hydrogen halide.<sup>80</sup> On the other hand, warm dilute mineral acids, such as dilute hydrochloric and sulphuric acid, dimerize indene. A similar polymerization to diindene takes place, though more slowly, with weaker acids, such as phosphoric acid<sup>81</sup> and warm glacial acetic acid.<sup>82</sup> Dimerization can also be induced by concentrated aqueous zinc chloride solution or a 30 per cent solution of aluminum chloride in water.<sup>83</sup>

Indene is converted by a solution of iodine in aqueous potassium iodide into polymers of high molecular weight, but partial iodination also occurs. Stobbe and Färber<sup>84</sup> isolated an iodododecaindene,  $C_{108}H_{95}I$ , which melted at 200-210°C. with decomposition.

As mentioned before, polymerization of indene is catalyzed by a number of anhydrous metallic halides, including stannic chloride, antimony penta- and trichlorides, titanium tetrachloride and boron trichloride. Of these catalysts, stannic chloride and antimony pentachloride appear to be so active that inert diluents are necessary. Bruson<sup>85</sup> polymerized pure indene in chloroform solution by anhydrous stannic chloride at 10°C. Reaction is complete in 5-10 minutes and the product is a white, amorphous, non-crystalline powder, melting at 248-250° and having a molecular weight (in benzene solution) of 2900-3000, corresponding to  $(C_9H_8)_{32}$  to  $(C_9H_8)_{36}$ . This polymer is soluble in benzene, chloroform, carbon bisulphide, and pyridine, but only very slightly soluble in alcohol, acetone, and ether. The polyindenes obtained by the action of stannic chloride have been studied by Staudinger and his collaborators.<sup>86</sup> The influence of the concentration of indene in benzene solution on the yield and character of the polyindenes formed by the same amount of stannic chloride (2 per cent by volume of indene) at 5° is shown in Table 17.

Concentration of Indene in Benzene Solution, %	Yield of Polyindenes, %	Characteristics of Polyindenes	
		Mol. Wt	Softening Point, °C
50	100	3670-3850	220
10	80	3240-3470	205
1	50	2350-2300	195

A number of experiments on the polymerization of indene in toluene solution (20 grams of indene in 250 cc. of toluene) at different temperatures, with the same amounts of stannic chloride as polymerizing agent, showed that lower temperatures favor the formation of materials of high molecular weights. The results of these experiments, which were all of 8 hours duration and in which the yield of polyindenes was in every case almost quantitative, are given in Table 18.

All the polyindenes investigated by Staudinger and his collaborators were amorphous and hemicolloidal<sup>87</sup> in character.

Whitby and Katz<sup>88</sup> studied the polymerization of indene in chloroform solution by antimony pentachloride and stannic chloride, respectively. The resulting white amorphous products were fractionally precipitated by alcohol from benzene solution. Bromine-absorption tests (24 hours in dark in chloroform solution with 0.07*N* bromine in chloroform) showed that all fractions were unsaturated and absorbed 2 bromine atoms per molecule. Some of their results are shown in Table 19.

TABLE 19 —*Polyindene Polymerized by Stannic Chloride in Chloroform.*

7	952	164-167	1.93

Oxygen and certain unstable oxygenated derivatives of the peroxide type appear to catalyze the transformation of indene to resins.<sup>89</sup> An ozonized mixture of disobutylenes is an example of the latter type.<sup>90</sup> According to Ward, Jordan and Fulweiler,<sup>91</sup> the formation of gum from indene fractions is catalyzed by oxygen (especially in the presence of mercaptans) and is inhibited by phenols. On treatment with perbenzoic acid, indene yields both oxygenated and polymerized derivatives.<sup>92</sup> For the polymerization of indene Brusson<sup>93</sup> suggested the use of an aryldiazonium fluoroborate, e.g., phenyldiazonium fluoroborate,  $C_6H_5-N_2BF_4$ .

**Properties of Polyindenes.** As already stated, the polymerization products of indene form a series, their melting points rising uniformly with increasing molecular weight. Dielectric constants and refractive indices of the polymers also vary uniformly with increasing molecular weight.<sup>94</sup> Employment of such catalysts as sulphuric acid generally furnishes a mixture of polymers containing upwards of 50 members of the polymeric series. Although a rough fractionation may be effected, e.g., by fractional precipitation from solution, it is almost impossible to separate chemical individuals from such a complex mixture. Only dundene has been actually isolated in a relatively pure condition. The mixture of polymers is conveniently classified under the generic name of *polyindene*. The latter is a white powdery substance of a hemicolloidal character, the lower members being

<sup>87</sup> As opposed to eu colloidal. See Chapter 4 for discussion of colloidal properties of polymers in general.

more easily liquefied and less viscous than the higher members. When polyindenes are heated above 300°C., a certain amount of depolymerization occurs and lower polyindenes, diindene and indene itself, are produced in proportions that vary with the conditions.<sup>56</sup>

**Molecular Structure of Polyindene.** Staudinger<sup>57</sup> has put forward this general formula to explain the constitution of polyindenes:

Polymerization mechanism is represented as the formation of long chains connected through the ethylenic linkages. The unsaturated end valences (represented thus, C . . . .), Staudinger considered to be satisfied possibly by the combination of 2 or more such chains into a ring.<sup>57</sup> This explanation of their structure has been criticized by Whitby and Katz<sup>58</sup> on the ground that polyindenes are unsaturated and capable of combining additively with 2 atoms of bromine per molecule. These workers, on the other hand, believe that the polymerization of indene is best represented as proceeding stepwise by the regular addition of successive molecules of monomer to the double bond present at the stage of polymerization immediately preceding, according to the following scheme:

Whitby and Katz consider this explanation of the reaction mechanism to be in accord with the observed facts of thermal polymerization of indene and diindene mixtures and depolymerization of polyindenes, and is not incompatible with the known properties of diindene.

Polymerization of indene is a unimolecular reaction, according to Tammann and Pape,<sup>59</sup> who suggest that the molecules undergo some change before union, the rate of this transformation determining the speed of the entire series of reactions. Increase in pressure is accompanied by an increase in the reaction velocity and a decrease in the initial polymerization temperature.

The constitution and properties of diindene are of importance in explaining the

general structure of indene polymers. Diindene is a crystalline solid (m.p. 57-58°C.) which readily adds bromine (without the elimination of hydrogen bromide) to yield a dibromide (m.p. 120-121°C.). Diindene can be polymerized by heat or by catalysts, such as sulphuric acid or antimony pentachloride.<sup>100</sup> A mixture of diindene and indene yields trindene on heating. On this account, it is apparent that diindene is an unsaturated hydrocarbon with 1 double bond.

Of the several possible constitutions for diindene, only the structure in which it is represented as 2- $\alpha$ -hydrindylindene, suffices to explain its reactions:

It can be oxidized by chromic acid to yield  $\alpha$ -hydrindene<sup>101</sup> and the ready formation of a monoisitroso derivative with amyl nitrite and sodium ethoxide<sup>102</sup> proves the presence of a reactive methylene group (in the unsaturated five-membered ring system).

The polyindenes can be hydrogenated to hexahdropolyindenes by treatment with hydrogen under high pressure in the presence of a nickel catalyst at 270°C.<sup>103</sup> Complete hydrogenation at this temperature is always accompanied by degradation of more-highly polymerized compounds. The hexahdropolyindenes are white powdery substances, stable towards chemical reagents. Hydrogenation of indene itself under high pressure in the presence of ferric oxide and kieselguhr yields about 80 per cent of resinous polymers.<sup>104</sup>

**Homologues of Indene.** Boes<sup>105</sup> found a mixture of three isomeric methylindenes in the fraction of coal-tar naphtha boiling between 200° and 210°C. The mixture of isomers was at first water-white, but soon turned yellow. Concentrated sulphuric acid resinified the methylindenes, the resulting polymers being free from sulphur and possessing varying degrees of molecular complexity. Hydriodic acid converts methylindenes into resinous polymers. Nitric acid resinifies these hydrocarbons and also partly oxidizes them to a mixture of acids, among which Boes identified hemimellitic and trimellitic acids.

## Chapter 6

### Production of Cumarone Resins

Technical cumarone resins consist principally of mixtures of cumarone and indene polymers, obtained by proper treatment of coal-tar naphtha fractions boiling between 150-200°C. In Chapter 5 the general properties of these substances were described, the discussion presented there indicating that controlled polymerization is necessary to obtain high-quality products. In the commercial production of cumarone resins considerable skill and experience are required. Unless each stage of the process is carefully carried out, sticky, dark-colored materials of limited applicability result. For most purposes cumarone resins should be clean, odorless, pale in color, and possess a melting point of about 135°C. The tars and acid sludges obtained in the usual course of acid-refining of coal-tar naphtha (without special means of separation of the resin contained in them) are not to be confused with cumarone resin, which is a special product.

Experiments on the production of cumarone resin have been described by Ellis and Rabinovitz.<sup>1</sup> A fraction of solvent naphtha boiling between 160-180°C. was treated with 1 per cent of sulphuric acid (sp. gr. 1.84) with good agitation for several hours, the temperature of the mass not rising above 35°C. throughout the operation. The mixture was washed free of acid and distilled with superheated steam to remove naphtha and naphthalene, yielding a residue possessing the consistency of molasses. This soft material was then distilled under 29 inches vacuum up to 180°C. with a loss of 57.5 per cent of its weight. The product was a resin which became plastic at 38°C. and melted completely at 71°C. It had a saponification number of less than 0.2 and an iodine number of 38-43.5. The viscous oily distillate had an iodine number of 28.5. Ellis and Rabinovitz tried a number of other catalysts for the production of resinous polymers, but, with the exception of silver oxide, none was as effective as sulphuric acid. At the boiling point of the naphtha, silver oxide caused the formation of a resin which was harder than that obtained with sulphuric acid. A bright silver mirror formed on the walls of the containing vessel during the reaction.

Some factors involved in the manufacture of technical cumarone resin have been discussed by Marcusson,<sup>2</sup> who stated that such resins can be improved by (1) using only the fraction of solvent naphtha boiling between 160° and 180°C. as raw material, (2) drawing off the sulphuric acid as quickly as possible after polymerization, (3) removing acid resin completely, and (4) separating oily materials from the reaction product by steam distillation under reduced pressure. Marcusson considered that the low melting point of technical resins was due, at least partly, to the indene content of the naphtha, and that higher-melting resins might be obtained by removing indene prior to polymerization. In consequence of this, Kattwinkel<sup>3</sup> attempted to find catalytic agents capable of selectively polymerizing cumarone, but apparently without success. Phosphorus pentoxide

<sup>1</sup> Carleton Ellis and L. Rabinovitz, *Ind. Eng. Chem.*, 1916, 8, 797.

and boric anhydride retarded the polymerization of solvent naphtha by sulphuric acid, possibly owing to the formation of ester-like compounds with the phenols present.

According to Stein,<sup>4</sup> the hardness of cumarone resin is dependent upon the degree of polymerization, and its melting point can be raised by using more concentrated sulphuric acid as polymerizing agent.

In a study of the production of resins from a coal-tar naphtha boiling between 155-185°C., Hirano<sup>5</sup> found that the naphtha should previously be washed with caustic soda solution (sp. gr. 1.22) to remove tar acids, and then with dilute sulphuric acid (sp. gr. 1.20) to remove bases. After drying the naphtha a yield of 9.53 per cent of cumarone resin was obtained by slowly adding 5 cc. of concentrated sulphuric acid to 100 cc. of the well-stirred, purified naphtha. The initial temperature of the oil should be as low as possible and rise in temperature during reaction should be avoided. A paler resin was obtained by thoroughly washing the reaction product with alkali. Other polymerizing agents were also tried. Five cc. of stannic chloride with 100 cc. of naphtha gave 6.06 g. of a hard, pale resin, melting at 85°C.; and 10 g. of aluminum chloride furnished 32.5 g. of a soft, dark resin, melting at 38°C.

German practice for the manufacture of cumarone resins has been described by Glaser.<sup>6</sup> The naphtha was first carefully freed from bases and phenols, and the polymerization then carried out by intimately mixing concentrated sulphuric acid with the naphtha. For this purpose mechanical agitators were employed, since agitation by air resulted in large losses of naphtha. The acid was slowly added in small portions up to a total of about 5 per cent of the charge by weight. During polymerization, a diminution in volume to the extent of 8-12 per cent occurred.

Burda<sup>7</sup> prepared cumarone resins directly from the heavy benzol fraction of coal-tar without the removal of phenols and pyridine compounds. The yield of resin was found to vary with the amount of concentrated sulphuric acid used as polymerizing agent. With less acid, the yield was smaller but the resin was of light color. Repeated treatment of the heavy benzol fraction with 0.5-1 per cent of concentrated sulphuric acid, distilling off volatile hydrocarbons after each addition of acid, yielded at first hard resins, and, later, softer ones. The soft resins could be made harder by heating at 150-180°C. for 20-90 minutes.

The total amount of resin-forming material in solvent naphtha can be determined by adding gradually 2 cc. of concentrated sulphuric acid to 100 cc. of naphtha in a separatory funnel. After running off the acid layer and steam distilling the naphtha, the residue is dehydrated and weighed.<sup>8</sup>

#### COMMERCIAL PRACTICE IN THE PRODUCTION OF CUMARONE RESINS

The commercial production of cumarone resin involves the following distinct steps:

1. Refining the solvent naphtha.
2. Pretreatment of naphtha to remove water and, in some cases, undesirable reactive hydrocarbon constituents.
3. Polymerization.
4. Separation of catalyst (that is, sulphuric acid) and tar sludge.
5. Neutralization of oil.

<sup>8</sup> I. I. Burda, *Ukrain. Khim. Zhur.*, 1929, 4 (Tech.), 257; *Brit. Chem. Abs. B.* 1930, 649.

6. Washing the resin-containing oil.

7. Distillation of oil and recovery of resin as residue.

In the early days of the industry products of low quality were often obtained, but with improved technic and increased attention to details the resin has been greatly improved. The production of cumarone resin in the United States represents a comparatively recent development and the methods adopted reflect to some extent the practice in those countries where the industry was established earlier.

**Refining the Solvent Naphtha.** The solvent naphtha commonly used for the production of cumarone resins is obtained by the fractional distillation of crude coal tar. In older practice, a fraction boiling between 150-200°C. was employed, but the modern tendency is to use narrower cuts, especially those boiling between 160-180°C., since these fractions are rich in cumarone and indene.<sup>9</sup> Polymerization of lower-boiling constituents of coal-tar yields dark resins which are in no way comparable with true cumarone resins. Sometimes the fractionation is regulated so as to furnish a raw material of practically constant cumarone-indene content, or different fractions may be mixed. A raw material containing 30 per cent of resin-forming constituents is stated<sup>10</sup> to be suitable, but fractions having a content of resin-forming substances as high as 80-90 per cent have also been used.<sup>11</sup> In any case the product of the first distillation of coal-tar contains too many impurities and should be very carefully redistilled, preferably in column stills. Only by starting with a sharply fractionated naphtha can high-grade resins be obtained. After careful fractionation, the naphtha is refined to remove phenols, tar acids, naphthalene, and the like. Naphthalene can be removed by freezing and pressing,<sup>12</sup> or by distilling a mixture of the naphtha and a higher-boiling oil (e.g., wash-oil of boiling point 230-330°C.), so that the naphthalene is retained by the residual oil.<sup>13</sup> Phenols are removed by washing with a caustic soda solution, and bases (pyridine and its homologues) by extracting with dilute sulphuric acid. The extraction of bases may be combined with a preliminary polymerization treatment for the removal of dark, resin-forming hydrocarbons by the use of about 5 per cent of sulphuric acid (sp. gr. 1.53).

**Pretreatment and Drying of Naphtha.** A preliminary treatment with sulphuric acid of somewhat lower concentration, or in quantity less than required for the resinification of cumarone and indene, serves to dry the naphtha and also to remove certain readily polymerizable hydrocarbons which yield dark tars.<sup>14</sup> Both objects may be achieved by agitating the naphtha with about 4 per cent by volume of sulphuric acid of 1.53 specific gravity for 45 minutes<sup>15</sup> or by using 0.1-0.5 per cent of more concentrated acid (sp. gr. 1.71-1.84).<sup>16</sup> Under these conditions most of the resins formed separate with the acid sludge and are withdrawn.<sup>17</sup> The naphtha may be neutralized with about 5 per cent by volume of a 15 per cent caustic soda solution, separated from alkali sludge, washed with 20

<sup>17</sup> Sulphur trioxide has been suggested for removing resins from crude benzene. See W. Gluud, German P. 551,867, 1930, to Ges. für Kohlentechnik m. b. H.; *Chem. Abs.*, 1932, 26, 4944.

per cent of its volume of water and distilled before proceeding to the final polymerizing treatment.<sup>18</sup> In one large-scale method, the wet naphtha is agitated with 0.5 per cent by volume of sulphuric acid (specific gravity 1.71) and the acid, after settling, is drawn off from the dry naphtha. This acid, on account of its dilution by water from the oil, does not cause polymerization of cumarone and indene. Purification by removal of unessential hydrocarbons can also be effected by selective treatment with 2-5 per cent of chlorine, followed by removal of the chlorinated products by distillation.<sup>19</sup>

**Polymerization.** In order to produce hard resins of high melting point and light color, the polymerization of cumarone and indene in solvent-naphtha fractions must be carefully controlled. A dark-colored, soft, sticky resin has comparatively few applications and only light-colored resins are acceptable in varnish making. Hence, the mere production of polymerized material will not suffice unless the product possesses color and hardness comparable with the best natural resins.

In large-scale operations sulphuric acid is employed almost exclusively as the polymerizing agent, for its cheapness and efficiency outweigh any disadvantages connected with its use. However, certain other catalysts will perhaps be used for light-colored, high-melting resins. Such substances as aluminum chloride, ferric chloride, stannic chloride, acid ferric sulphate, and boron trifluoride have been found applicable.

The most important factors to be considered in producing resins by the use of sulphuric acid are (1) the strength and quantity of acid added, (2) the rate of addition of the acid, (3) the degree of admixture of acid with naphtha, (4) the temperature control of the reacting mass, and (5) the duration of the polymerization. The acid must be sufficiently concentrated to yield high-melting resins, but not enough to form dark-colored or sulphonated compounds. The use of too-dilute acid produces soft resins because of extensive low-polymer formation. Owing to the highly exothermic nature of the reaction (said to be caused mainly by the polymerization of indene), slow addition of the polymerizing agent with violent agitation and efficient cooling of the reaction mixture are essential. The process, as usually carried out, consists in running a very slow stream of sulphuric acid of about 93 per cent strength into the solvent naphtha, the mixture being violently stirred by efficient agitators. Thorough means of cooling must also be provided to keep the mixture at about 0°C. during the reaction. The use of an inert diluent also serves to minimize overheating. In any case, the temperature should be kept below 20°C. and may even be lowered to -20°C. A lower temperature of polymerization produces resins of lighter color, and at the same time increases the yield.<sup>20</sup> The concentration and quantity of sulphuric acid used vary somewhat, and probably depend upon the efficacy of mixing, cooling and (more particularly) on the time of reaction. In general practice 0.2-1.0 per cent by volume of 66° Bé sulphuric acid (sp. gr. 1.84) is used,<sup>21</sup> although 1-3 per cent by volume of 62° Bé acid (sp. gr. 1.75) may also be employed at a temperature not exceeding 30-35°.<sup>22</sup> However, by intimately mixing the constituents, employing efficient refrigeration and cutting short the period of reaction, larger quantities of more-concentrated acid may be advantageously employed. The use of 2-5 per cent by volume of 66° Bé sulphuric acid (sp. gr. 1.84) at temperatures between 0°

and 15° is satisfactory if the reaction is stopped after 10 minutes by the addition of water.<sup>23</sup> The time of reaction can even be reduced to 10 seconds, if the mixture of naphtha and 3 per cent by weight of 66° Bé acid is thoroughly emulsified and cooled.<sup>24</sup>

Typical polymerizing equipment for the treatment of 3000 gallons of dried naphtha (containing 30 to 40 per cent of resin-forming material) consists of a vessel fitted with coils having a cooling surface of 3000 square feet, through which cold brine can be pumped from an insulated tank of 10,000 gallons capacity. The quantity of 66° Bé sulphuric acid used is 90 to 150 gallons for a charge of 3000 gallons of dry naphtha. The oil is first cooled to -10°C. and the acid is added in

2- to 3-gallon portions until 15 gallons have been introduced. The temperature is carefully watched and if it rises above 10°C., the addition of acid is stopped temporarily. The progress of polymerization is watched by determining from time to time the specific gravity of the mix. Since the oil increases in specific gravity during polymerization, the point of no-further-increase will indicate the end of the reaction.

The polymerizing-acid rapidly settles to the bottom of the naphtha, therefore an ordinary paddle agitator is not as satisfactory for mixing as one which constantly elevates the acid from the bottom to the top of the naphtha layer.<sup>25</sup> A rapidly revolving vertical conveyor enclosed by a tube (open at each end) serves to accomplish the mixing. More often, however, mixing is effected by drawing

<sup>23</sup> W. R. Gerges, U. S. P. 1,679,214, July 31, 1928, to the Barrett Co.; *Chem. Abs.*, 1928, 22, 3792

<sup>25</sup> A mixing apparatus is also described by Miller in U. S. P. 1,670,593, May 22, 1927; *Chem. Abs.*, 1928, 22, 2379.

naphtha and acid from the bottom with a pump and returning the mixture to the top of the polymerizing-vessel. (See Fig. 44.) For the treatment of a 3000-gallon batch of naphtha, a 12-inch pipe running from the bottom to the top of the tank may be used, with the liquid circulated by a centrifugal pump at the rate of 3500 gallons per minute.

**Separation of Acid Tar.** After the polymerizing action has been completed, the oil is allowed to stand so that the heavy tar may settle out. The amount of tar is usually about 2 per cent of the original naphtha, and consists principally of a sludge of acid and sulphonated substances with some entrained naphtha. It is essential that this tar be removed completely and as quickly as possible, otherwise, discoloration of the resin results. At a temperature of 5°C., which seems to be the most satisfactory, 45 minutes are required for the settling of the sludge in a 3000-gallon batch of naphtha. Settling is greatly facilitated, according to Gerges,<sup>26</sup> by dilution of the mixture with 10 volumes of cold water. Under these conditions, separation is complete in 10-15 minutes and the mixture of aqueous acid and sludge suspension can be easily drawn off.

**Neutralization.** When the sludge has been removed, the oil remaining is neutralized with caustic soda solution of specific gravity 1.2-1.8.<sup>27</sup> Use of a weaker solution will cause emulsification and thus prolong the period of settling. The neutralization may be conducted in the polymerization tank or it may be carried out in a cone-shaped settling tank, in which the subsequent washing with water will also take place. If careful separation of acid sludge has been made, the amount of caustic soda solution required will not exceed 1 or 2 per cent of the volume of the batch.

**Washing.** After neutralization is complete, the soda solution is allowed to settle and is drawn off. The neutralized oil is washed free of most of the soluble matter, which consists principally of sodium sulphate and sulphonates and traces of iron salts. Very complete removal of sodium sulphate is necessary since the presence of appreciable amounts of this salt in the resin causes it to whiten on contact with water. The ash content of the resin should be less than 0.3 per cent. For some purposes cumarone resin having an ash content of less than 0.1 per cent is specified.

The washing operation consists of mixing the resin solution with water and agitating by stirrers or compressed air. The settling and separating steps involved in this operation cause a loss of material equivalent to 5-10 per cent of the total naphtha, most of the loss being caused by the formation of emulsions. It has been found that emulsification can be prevented by the use of a 3 per cent aqueous solution of sodium chloride, ammonium chloride, calcium chloride,<sup>28</sup> or hydrochloric acid.<sup>29</sup> About 20 per cent by volume of dilute brine or acid is added to the oil, which is heated to 60-70°C. to facilitate the separation of wash water. Washing may be effected without the use of agitation by introducing water over the oil in the form of a fine spray and allowing it to settle.<sup>30</sup>

**Distillation.** As the final step in the manufacture of cumarone resin, the washed naphtha is distilled off and the resin is obtained as a residue. The distillation is carried out in a steam-jacketed vacuum still equipped with a draw-off and steam-jacketed valve. At the bottom of the still are pipes for the introduction

of live steam and also a small steam-coil for heating. Naphtha is first withdrawn under a vacuum of about 28 inches. As soon as the flow of distillate begins to drop, live steam is introduced into the bottom of the still and whatever naphthalene is present appears in the receiver first. At this point, the condenser water, which is cold during the distillation of the naphtha, is warmed to about 70-80°C. to prevent choking of the lines. Following the naphthalene, there distils over a heavy oil (boiling at 320-330°C. at atmospheric pressure), which is possibly a by-product of the polymerization of indene. The quantity of this oil depends upon the polymerizing conditions, a greater amount of oily polymers being produced at higher temperatures and with dilute sulphuric acid. Removal of this material is imperative for the manufacture of a high-melting resin and can best be accomplished by steam distillation under high vacuum. However, high-vacuum distillation without the use of steam is preferred by some,<sup>21</sup> because water has a tendency to become emulsified in the resin so that an opaque product results.

According to varnish makers, cumarone resin cannot stand exposure to temperatures above 275°C. without darkening. In this respect it is more sensitive than some of the natural resins. It is not known definitely whether the darkening is due to the thermal instability of the resin itself or to traces of sulphonated substances, but the latter explanation is more likely. From a practical standpoint it is thus important to avoid the use of temperatures exceeding 250-275° during distillation and better results are obtained by operating at lower temperatures (200-250°). This is particularly the case in the production of a varnish resin, where color is of prime importance.

During distillation the melting point of the still-residue is determined from time to time and distillation is continued until the melting point is sufficiently high (usually 135° for a varnish-grade material). The resin is then run into containers at the still temperature. It may be flaked with a chill roll or chipping machine.<sup>22</sup> The distillation of 3000 gallons of polymerized oil may last 60 hours, use of live steam constituting the heaviest item of total manufacturing cost.

To obtain pale elastic cumarone resins it is not only necessary, according to Schneider,<sup>23</sup> to keep the temperature low during the polymerization process, but also during the evaporation of the solvent. High-boiling solvents can be evaporated at comparatively low temperatures by passing a gentle current of air over the material. By keeping the temperature at 90°C. a very pale cumarone resin with a softening point of 80°C. can be made, with an evaporation loss of only 2 per cent of solvent.

#### BY-PRODUCTS OF CUMARONE RESIN MANUFACTURE

A number of by-products are obtained in the manufacture of cumarone resins. The high-boiling oils (b.p. 150-300°C. *in vacuo*) obtained during the distillation of the resin solution are probably low polymers of indene. They have found little industrial application, although Lilienfeld<sup>24</sup> proposed to use them as lubricants, insulating material, transformer oil, for pharmaceutical purposes, or as plasticizers for cellulose ethers. Dennis<sup>25</sup> utilized the by-product oils for the preparation of a cleansing mixture by emulsifying them with soap solution.

A so-called "paracumarone soap" may be produced from the first wash of the

<sup>21</sup> I. H. Jones, U. S. P. 1,684,868, Sept. 18, 1928, to the Koppers Co.; *Chem. Abs.*, 1928, 22, 4845.

neutralized solvent naphtha (after polymerization and separation of the acid).<sup>36</sup> By steam-distilling until foaming prevents further treatment, this first wash will yield about 37 per cent of paracumarone soap, 50 per cent of water and 13 per cent of naphtha. A typical paracumarone soap has a total ash content of 10.5 per cent, of which about 6.03 per cent consists of sodium sulphonates. "Sludge paracumarone" is a similar product containing 9.5 per cent of ash (mainly sulphonates).

#### MISCELLANEOUS PROCESSES

A continuous process for the manufacture of cumarone resins has been described by Miller and Hill.<sup>37</sup> Coal-tar naphtha and concentrated sulphuric acid are run separately into a jacketed reaction chamber fitted with a stirrer. The mixture then passes to a settling-tank where separation into two layers takes place. The naphtha, containing dissolved resins, is led into a storage tank and is neutralized and distilled in the usual way. The sulphuric acid is led back into the reaction vessel or to storage. In another continuous process, Miller and Hill subjected

FIG. 45.—Emulsifying Apparatus for the Polymerization of Cumarone. (S. P. Miller and J. B. Hill.)

solvent naphtha to rapid polymerization by emulsifying it with a solution containing a catalyst such as sulphuric acid or aluminum chloride.<sup>38</sup> They stated that the quality of the resin obtained in a continuous-polymerizing process is materially improved if the rate of flow of the reactants through the apparatus is increased. However, at high rates of flow, complete polymerization is conditioned by very intimate contact between the hydrocarbon and the polymerizing agent. By rapidly passing a mixture of naphtha and catalyst between rotating surfaces (spaced 0.005 to 0.10 inch apart and moving relative to one another at a velocity greater than 50 feet per second) very intimate contact is obtained and a time of contact of about 10 seconds is sufficient (see Fig. 45).

In an apparatus described by Miller<sup>39</sup> for the preparation of synthetic resins from solvent naphtha, the required quantity of cooled oil is introduced automatically into a vessel where it is agitated with sulphuric acid, aluminum chloride, or another polymerizing agent. The oil is treated in successive batches, but since all the operations are automatically controlled, the process is in effect continuous. After polymerization, the mixture is withdrawn, spent polymerizing agent and tar are separated, and the oil is neutralized with alkali and distilled.

Contrary to usual procedure, Roberts<sup>40</sup> proposed to polymerize cumarone and indene in solvent naphtha by use of relatively large proportions of concentrated sulphuric acid for short periods of time, so that at least 10 times as much acid is present as cumarone and indene in the naphtha at any instant. The naphtha is passed continuously through a large volume of concentrated sulphuric acid and the solution of polymerized resin is withdrawn continuously from the top. The acid in the polymerizing chamber is cooled with coils and the heat generated by the polymerization is absorbed completely by the large excess of sulphuric acid. Roberts stated that sufficient sulphuric acid must be present to prevent the heat of reaction from causing a temperature change of more than 30°C. The resins obtained by this polymerization procedure are said to be of lighter color, and to melt about 20°C. higher than those obtained by other processes.

In the process of Wendriner,<sup>41</sup> solvent naphtha is subjected to two successive treatments with sulphuric acid of different concentrations. The naphtha, after being freed from tar acids and bases, is first mixed with 3-5 per cent by volume of 60° Bé sulphuric acid and then 66° Bé sulphuric acid (not more than 0.25 per cent by volume) is continuously added in a thin stream. During the latter step the mixture is agitated vigorously and the temperature allowed to rise to 110-120°C. Stirring is continued until the temperature has fallen to 100° and the mass is allowed to settle. After the acid is removed, the mixture is neutralized and then freed from sodium sulphate. Subsequent distillation with steam produces a clear resin.

Wendriner discovered later, however, that by allowing the temperature to rise secondary reactions took place with the formation of insoluble resins and sulphonated products. By maintaining the temperature at 40-50°C., he not only avoided these reactions but also was able to carry out the polymerization with 66° Bé acid alone. The resin thus produced had a higher melting point and was citron to amber-yellow in color. Wendriner found that if tar acids and bases are not removed prior to polymerization of the cumarone, the resin obtained is not as pure, and more sulphuric acid (0.5 per cent) must be used.

Karns<sup>42</sup> prepared resins which had a lighter color and a greater degree of hardness and transparency than previously obtained, by treating coal-tar distillates, boiling at 140-200°C., with aluminum chloride (0.25 to 1.25 per cent of the weight of oil) at a temperature of about 45°C. The distillate is given a preliminary treatment with a small quantity of sulphuric acid (0.1 to 1.0 per cent of the weight of the oil). The acid is then neutralized and the oil distilled. The treatment with sulphuric acid is insufficient to affect cumarone and indene, but it polymerizes such easily resinified substances as cyclopentadiene, which tend to form dark resins.

In the preparation of very light-colored cumarone resins, Jones<sup>43</sup> employed an initial polymerization to remove unsaturated substances productive of dark resins. The preliminary polymerization is carried out by treatment with about 5 per cent by volume of 50° Bé acid for 45 minutes, after which the sludge and spent acid are separated and the naphtha washed with caustic soda solution, then with water, and finally distilled with steam. The condensate (usually about 90-95 per cent of the original naphtha) is then carefully fractionated, and a cut taken from 150-200°C. is polymerized. The fractionation step is stated to eliminate darkening and softening constituents from the final resin. In an analogous procedure, the addition of ammonium sulphate to the sulphuric acid used in the

<sup>42</sup> H. C. Karns, U. S. P. 1,541,226, June 9, 1925, to the Koppers Co.; *Chem. Abs.*, 1925, 19, 2277.

<sup>43</sup> I. H. Jones, U. S. P. 1,684,868, Sept. 18, 1928, to the Koppers Co.; *Chem. Abs.*, 1928, 22, 4845.

second polymerization is said to be of value in obtaining light-colored products. It is also stated that practically colorless resins result if a mixture of 15 parts of sulphuric acid, 4 parts of acetic acid and 1 part of water is used as polymerizing-catalyst.<sup>44</sup>

Cline obtained light-colored cumarone resins from oils which ordinarily yield dark resins.<sup>45</sup> The essential feature of his procedure is a preliminary treatment of crude coal-tar naphtha by refluxing it for an hour with 5 per cent of litharge. This treated oil is then removed by decantation and subsequently vacuum-distilled in contact with an alkaline material. The distillate coming over at temperatures up to 200°C. (at atmospheric pressure) is polymerized with sulphuric acid (sp. gr. 1.83) in the presence of refined naphtha as a diluent. This method recovers 80-85 per cent of the total polymerizable constituents as resin.

In the process of Rabinovitz,<sup>46</sup> solvent naphtha (b. p. 160-180°C.) is treated with a slow stream of sulphuric acid (sp. gr. 1.84) under good agitation. The acid is withdrawn and the naphtha washed with a 5 per cent alkali solution. The solvent naphtha is then distilled with superheated steam and the viscous residue is hardened by distillation under a vacuum of 29 inches until the temperature reaches 180°C. The resulting pale, hard resin has an iodine number of 47.

Meyer<sup>47</sup> prepared a light-colored resin of high softening point by polymerizing cumarone and indene with acid in the usual manner and then neutralizing the acid present by vigorously agitating it with a slight excess of powdered alkali or alkaline-earth carbonates, preferably with the addition of a small quantity of barium or sodium peroxide. The neutral liquid was then separated by decantation, filtration, or centrifuging and the volatile constituents removed by distillation.<sup>48</sup>

Anhydrous metallic chlorides, such as aluminum chloride or ferric chloride, were used by Demant<sup>49</sup> for the polymerization of the unsaturated compounds in crude benzene to yield resinous products which soften above 100°C. After removal of the catalyst by washing with water, the resins are obtained by distilling off the benzene. They can be used for varnishes without further purification.<sup>50</sup> The polymerization is effected without external heating and, if necessary, with cooling. Hydrated metallic chlorides can be used to produce high-melting cumarone resins. Stirring coal-tar distillates with small quantities of hydrated aluminum or ferric chlorides causes polymerization without external heating.<sup>51</sup> Supan<sup>52</sup> employed ferric chloride for the production (from crude benzene fractions) of resins having a softening point as high as 170°C. For example, 2 per cent of crystalline ferric chloride is added gradually to a crude benzene fraction (b. p. 160-180°C.) heated to 50°C., and the mixture is cooled to prevent too great a rise in temperature. On completion of the reaction, the liquid is washed with water and sodium carbonate solution, and the resin is separated by distilling off the unchanged liquid. Oil-soluble metallic chlorides, e.g., titanous chloride, have also been suggested as catalysts.<sup>53</sup>

In order to control the degree of polymerization of cumarone, Copthorne and

Tannehill<sup>64</sup> proposed the dilution of tar- and base-free solvent naphtha (b. p., 150-200°C.) with lighter naphthas (b. p., 130-150°). Another suggestion made by Tannehill was neutralization of the acid by ammonia gas to arrest polymerization while the resin is still in a highly fluid state.

A dilution method was also used by Emery.<sup>65</sup> A distillate containing as high as 80 per cent of cumarone and indene, prepared by fractional distillation, is polymerized and then diluted with petroleum benzine in order to facilitate removal of insoluble substances. The resin solution is then decanted, washed free of acid and distilled under high vacuum, live steam being used to remove heavy oils. Ostermayer<sup>66</sup> employed a similar cut rich in cumarone and indene as initial material, but diluted the polymerized material with petroleum distillates both higher and lower in specific gravity than petroleum benzine. The product obtained, when using petroleum distillate of low specific gravity, is of slightly lower melting point and not so clear as when heavier petroleum distillates (kerosene or wash oils) are employed; but the procedure is facilitated in the former case. Ostermayer stated that better control of the process is obtained by diluting the naphtha with petroleum distillates, either before or during the polymerization. However, the products are darker and of lower melting point than when dilution is effected after polymerization.

A clear, transparent resin of high melting point for use in varnishes is obtained by carrying out the polymerization in a mixture containing a relatively small quantity of crude solvent naphtha in proportion to the diluent (a coal distillate or petroleum distillate). Dilution serves to prevent rise in temperature. After the initial polymerization, additional small quantities of crude naphtha and catalyst are run into the batch until a final concentration of 25 per cent of polymers exists. Up to this point only 3-5 per cent of sulphuric acid (sp. gr. 1.83) is needed. Recovery of resin from here proceeds in the usual manner.<sup>67</sup> An improvement in this method consists in dispersing the sulphuric acid catalyst in the diluent and then adding the solvent naphtha at a controlled rate.<sup>68</sup>

Crude benzene was used by Schneider and Nettlebusch<sup>69</sup> to produce resins by the dilution method. The benzol was diluted with solvent naphtha or with an oil boiling at 200-230°C., and then mixed with sulphuric acid (80-93 per cent) at 10-40°C. Distillation yielded motor fuel, oil and resin.

A process of Jaeger and Bertsch<sup>70</sup> includes treatment of the naphtha with chlorine prior to polymerization. After phenols and bases have been removed and the naphtha has been partially purified by washing with a small amount of sulphuric acid, chlorine is introduced. Chlorine reacts with the unsaturated and saturated aliphatic and alicyclic compounds (including hydrindene, cyclopentadiene, dicyclopentadiene, styrene) as well as with sulphur compounds such as thioxene, and transforms them into high-boiling chloro derivatives, but cumarone and indene are practically unattacked. For example, a solvent naphtha boiling at 150-180°C. is treated with 1-3 per cent of chlorine, or with an equivalent amount of bromine.

The chlorine or bromine is introduced in gaseous form mixed with an inert gas, and a small amount of calcium carbonate is added to neutralize acidity. After chlorination, the solvent naphtha is distilled off from the higher-boiling chlorinated substances and is polymerized either under heat and pressure or by addition of concentrated sulphuric acid at temperatures below 25°C. The product is neutralized, washed with water and distilled *in vacuo*. After superheated steam has been blown through the still-residue, an almost colorless resin is obtained.

Hofmann and Stegemann<sup>61</sup> obtained cumarone resin by shaking cumarone oil for some hours at ordinary temperature with hydrogen fluoride, boron trifluoride, or with a mixture of hydrogen fluoride and an inorganic halide. The hydrogen fluoride can be expelled from the product by heat.

Modified cumarone resins, soluble in all proportions in commercial benzenes (even at ordinary temperatures) and also in drying oils, have been prepared by Rosenthal by polymerizing solvent naphthas (freed from phenols and bases) with catalysts such as stannic chloride, zinc chloride, concentrated sulphuric acid, ferric chloride, fluoboroacetic acid and antimony pentachloride, in the presence of meta-substituted aryl alkyl ethers of the general formula:

in which R and R' stand for alkyl groups and R'' represents hydrogen or an alkyl group.<sup>62</sup> Because of their solubility and stability to light, the modified resins have been suggested for the manufacture of oil varnishes. The properties of these resins vary with the catalyst employed. Fluoboroacetic acid yields nearly-colorless, high-melting resins soluble in drying oils. Lower-melting resins, light brown in color and also oil-soluble, are produced under the influence of sulphuric acid. The use of stannic chloride as a catalyst leads to the formation of very light-colored resins, insoluble in stand oils but soluble in ordinary drying oils. In one preparation, 1000 parts by weight of solvent naphtha (boiling point 163-182°C., containing 52 per cent of cumarone and indene and free from phenols and bases) are mixed with 86 parts of m-xylyl ethyl ether, and the mixture, heated to 40°, is treated with 10 parts by weight of fluoboroacetic acid. When the reaction is complete, the mass is diluted with 200 parts of xylene or purified solvent naphtha and treated, while hot, with 60 parts of calcium oxide or barium oxide. The resin solution is filtered from the precipitate and the volatile constituents are distilled off completely *in vacuo*. There are obtained 545 parts of a nearly colorless resin melting at 133° and readily soluble in cyclohexane, aliphatic and hydroaromatic hydrocarbons, linseed oil, tung oil, and stand oil.

In the polymerization of cumarone and indene in solvent naphthas, Weiss recommended the use of a special solid catalyst consisting of an acid ferric sulphate mixed with an absorbent such as fuller's earth.<sup>63</sup> Some advantages noted in the use of this polymerizing-catalyst are that the reaction is very gradual, with no tendency to superheating; the removal of polymerizing agent together with the tarry matter is quickly accomplished by filtration (in contradistinction to the long

period of settling required when sulphuric acid is used); and the absorption of dark-colored by-products by the porous carrier gives a light-colored product. The catalyst is prepared by thoroughly incorporating concentrated sulphuric acid (proportionately in excess of that necessary to form ferric sulphate) in a mixture of ferric oxide and absorbent earth, drying the mass, and powdering it to a size of about 20- to 30-mesh. Crude solvent naphtha (1 gallon), having a boiling range of 160-190°C., is vigorously agitated with about 0.5 pound of this catalyst for two hours at 55°C. or higher, after which the mass is filtered. The filtered solution is washed, first with a dilute alkaline solution and then with water. The resins are recovered by distillation under reduced pressure with superheated steam. The naphtha may be given an acid wash with sulphuric acid (sp. gr. 1.53) prior to the polymerizing treatment.

Cumarone resins of uniform properties, having melting points up to 135°C., were prepared by Sperr and Darrin<sup>64</sup> by polymerizing crude solvent naphtha under the influence of heat and pressure. The naphtha is heated to 100-450° under pressures ranging from 50-300 pounds per square inch for periods of from 1-10 hours, after which the volatile constituents are distilled off, the end-temperatures of the vapors being 150-300°C. The resulting mass is then blown with air or steam to remove high-boiling oils and the resin is drawn off. The rate of resinification is increased and the hardness of the resins improved by the use of catalysts consisting of strips of copper, silver, gold, or platinum immersed in the liquid.<sup>65</sup> The resins thus obtained are said to be harder than those from acid processes, and can be ground easily without sticking or gumming.<sup>66</sup> They possess a clear, reddish color and are useful for electrical insulation or for varnish making.

Cumarone resin produced by polymerization with sulphuric acid often retains acid substances. Ellis<sup>67</sup> removed these substances by fusing the resin with basic neutralizing agents in the absence of sufficient water to dissolve the basic material. The neutralized resins are then useful for the manufacture of concrete-floor varnishes and other coatings where a neutral resin is required.

The purification of crude cumarone resin was accomplished by Singer,<sup>68</sup> by washing with solvents (e.g., alcohol, acetone, or chlorinated hydrocarbons) to remove oily materials.

### MODIFIED CUMARONE RESINS

Modified cumarone resins are produced by adding to the solvent naphtha substances which alter the nature of the resin obtained. For instance, the condensation of solvent naphtha (b. p., 160-190°C.) to which phenols have been added, yields materials with disinfectant or therapeutic properties, and which are also useful for making lakes and dyes. For this treatment catalysts which have been employed include halogen acids, metallic chlorides<sup>69</sup> and acid salts.<sup>70</sup> A modified resin has also been produced by using the phenols already present in the solvent

naphtha.<sup>71</sup> It was found that the presence of phenols rendered the resin alcohol-soluble and therefore useful for lacquer preparations.

Very light-colored resins were prepared by Rosenthal by polymerizing solvent naphthas in the presence of phenols and under the catalytic influence of double compounds of boron trifluoride and carboxylic (or hydroxycarboxylic) acids.<sup>72</sup> When the reaction mixture contains phenols to the extent of 9 per cent or more of the quantity of indene present in the solvent naphtha, resins soluble in stand oil (prepared by heating linseed oil) are formed. The reaction is carried out by slowly adding small quantities (usually 1-5 per cent) of the fluoboro-fatty acids to the mixture of crude solvent naphtha and phenols at a temperature of about 60°C. For example, a resin soluble in linseed oil is prepared by allowing 2 parts of fluoboroacetic acid to run slowly for 2-3 hours into 100 parts of crude solvent naphtha (b. p., 155-192°C.), containing 58 per cent of cumarone and indene and 4 per cent of phenolic constituents. The temperature increases to about 60°C. (initial temperature is 35°) and stirring is continued for 6 or 7 hours. The mixture is then heated to 80-90°C. for one-half hour with the addition of 25 parts of xylene and 6-8 parts of barium oxide. The volatile constituents of the filtered reaction-liquid are then distilled *in vacuo* to furnish 55 parts by weight of an almost colorless resin which sinters at 140° and melts at 160°. By treating a mixture of 600 parts of solvent naphtha having a cumarone content of 20 per cent and an indene content of 36 per cent, and 21 parts of crude cresol (or 33 parts of  $\beta$ -naphthol) with fluoboroacetic acid as above, 320 parts of a very light-colored resin, melting at 147° and soluble in linseed oil, are obtained.

Rosenthal<sup>73</sup> also prepared light-colored, oil-soluble resins by condensing solvent naphtha containing cumarone and indene, with at least 10 per cent of phenols (calculated on the amount of resinifiable constituents present) with anhydrous or crystallized ferric chloride ( $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ ) as catalyst. The melting points of the resins depend upon the relative proportions of phenol and indene present. The following example concerns the treatment of a mixture of 200 parts (by weight) of a phenol- and base-free naphtha, boiling at 160-186°C. and containing 46.8 per cent of indene and 15.2 per cent of cumarone. Nine parts of phenol are introduced and then 14 parts of molten ferric chloride, at an initial temperature of 20°C. As reaction proceeds the temperature rises to 52-55°C. Stirring is continued for 6-8 hours and the temperature is maintained below 60°C. The mass is then diluted with 100 parts of xylene to remove iron compounds, and stirred with 10 parts of quicklime. The solvent is removed from the filtered resin solution by vacuum distillation, and a light resin is obtained which sinters at 125°C. and melts at 158°C.

Cumarone resin can be modified so as to increase its melting point by treating it with concentrated sulphuric acid in the presence of a solvent.<sup>74</sup> The solution is then neutralized with alkaline earths and the solvent removed by evaporation.

According to Staudinger,<sup>75</sup> hydrogenation of parindene resins renders them more resistant to heat and chemical action. Hydrogenation may be carried out under 50 to 70 atmospheres pressure and at about 270° employing a metal of Group 8 as catalyst.

Kessler<sup>76</sup> found that a coal-tar fraction (boiling at 150-250°C.), treated with an excess of formaldehyde<sup>77</sup> or other aldehyde in the presence of a trace of ammonia or caustic soda at 150°C., produced oils which dried on exposure to the air and slowly polymerized at this temperature. According to Hönel,<sup>78</sup> low-melting cumarone resins were rendered harder and higher-melting by heating them with 20 per cent of the condensation product of formaldehyde and p-amyphenol at 200°. A cumarone resin can be made less brittle by adding to it 5 to 10 per cent of drying oils, fats or waxes.<sup>79</sup>

Jaeger<sup>80</sup> recommended a phthalide or hydrogenated phthalide as a plasticizer for cumarone resin. About 12 per cent of phthalide is added to the fused resin, or the phthalide can be mixed with a solution of the resin to form a lacquer which dries to a flexible film.

Resinous products similar to cumarone resins have been obtained from naphtha fractions of higher boiling point than those ordinarily used. For instance a fraction boiling at 190°-240°C. has been utilized.<sup>81</sup>

Likewise light benzene fractions yield homologous resins. Demant<sup>82</sup> heated such fractions with sulphuric or phosphoric acid and obtained viscous oils which on further treatment could be used in varnish making. Krieger<sup>83</sup> treated a benzol fraction (80°-160°C.) with sulphuric acid, washed the product with water and alkali, and then distilled it in the presence of caustic soda. The still-residue yielded a brown, almost ash-free liquid (b. p., 260-360°C.), suggested as a lubricant.

The process of Damm for the purification of benzenoid oils yields resinous materials as by-products.<sup>84</sup> The oil is agitated with sulphuric acid (sp. gr. 1.71-1.83) and allowed to settle into 3 layers: acid, acid resin, and oil. After withdrawal of the acid, the remaining layers are neutralized with dilute caustic soda. The original impurities are thus liberated from the acid-resin layer in modified form and dissolved in the oil phase. The oil layer is then removed and the resin recovered from the acid-resin portion.

#### RESINS FROM ACID TAR

Strictly speaking, acid resins obtained from the sulphuric acid used in washing coal-tar light oils are not cumarone resins, but, since they are related, brief mention may be made of these products. The acid resins are usually obtained by adding water to the sulphuric acid used in refining coal-tar oils and then heating the solution without carbonizing the resins present. The dilute acid solution is extracted with a hydrocarbon such as benzol, and the resin, separated by evaporation of the solvent, may be utilized by adding it to solutions of other resins. By the above procedure, Hilpert<sup>85</sup> obtained a resin in the form of a bright yellow powder useful as a base for a quick-drying lacquer. The resin from the acid used to refine naphthalene is dark brown in color. Thorp and Thorp<sup>86</sup> recovered such resins in the following manner: The waste tar acid is agitated with from 1/2 to 1 volume

of water. On standing, a pasty mass of tar oil and resin settles out. This mass is washed with water and steam distilled. The resinous residue of the steam distillation is washed with alkali and dried. Schümmer<sup>87</sup> distilled the residue, obtained in a similar way, under reduced pressure and recovered the sulphur dioxide for conversion into sulphuric acid. Another method involves running the acid tars into boiling water.<sup>88</sup> The floating resin-layer is then drawn off and worked into a hard resin by treatment with steam, ammonia or alkali.

Kugel and Schwenke<sup>89</sup> neutralized the wash-acid from the refining of benzol with ammonia and diluted the precipitated resinous substances with benzol or solvent naphtha while agitating and cooling the liquid. After separation from the ammonium sulphate, the solvent is distilled from the resins.

In order to remove the resinous sludge from the sulphuric acid used for washing benzol, Still<sup>90</sup> heated the acid in a receptacle in the lower part of which a removable perforated tray is placed. After all the treated acid has been discharged from the still, the whole of the solid resin is lifted out on the tray. As a substitute for sulphuric acid in effecting removal of tar- and gum-forming impurities from benzene, the use of a slightly acidic potassium permanganate solution has been suggested.<sup>91</sup> This treatment causes the oxidation and polymerization of all olefinic substances in the benzene.

The still-residues from the redistillation of acid-treated and neutralized crude benzols (also carburetted water-gas tar, or "holder oil" and Pintsch gas "hydrocarbon drips") are high-boiling viscous sulphurous oils, which on prolonged heating are converted into pitch or resin.<sup>92</sup> This has been erroneously designated "cumarone resin" by some manufacturers. It is probable that the residues are derived from diolefinic compounds present in the original crude benzols.

Kattwinkel considers that sulphur present in the acid resin is in the form of neutral saturated sulpho-acid esters.<sup>93</sup> Upon removing the acid from such an acid resin and drying at 100°C., he obtained a dark violet-colored resin which could be easily pulverized. He extracted with aniline the powdered resin thus obtained and distilled the extract *in vacuo*. Removal of excess aniline by heating on a water bath left a pitch residue recommended for roofing compositions or for binders in coal or lignite briquettes.<sup>94</sup>

Sulphonated cumarone resins have been used to a small extent in various ways, such as in leather tanning,<sup>95</sup> in the production of viscose fibers<sup>96</sup> and in the form of their copper salts in mixtures for combating plant diseases.<sup>97</sup>

Benzol-still residues were used by Wagner in preparing cutting oils and gear-shield oils.<sup>98</sup> The residue is mixed with petroleum and water, heated to 80°C. and then allowed to cool and settle. The oily top layer is decanted, and the semi-solid material remaining is heated to 200°, whereupon the oily layer previously removed is again added to produce the cutting oil.

<sup>98</sup> F. W. Wagner, U. S. P. 1,534,554 and 1,534,555. Apr. 21, 1925, to Jones & Laughlin Steel Corp.; *Chem. Abs.*, 1925, 19, 1773.

Plastic materials have been prepared by Hoelzer<sup>99</sup> by heating under pressure either coal tar, lignite tar, or cumarone resin, together with a sulphurous solution obtained by extracting spent gas-purification materials with carbon disulphide or tar oils. Sulphuric acid, caustic soda, ferric chloride or manganous sulphate is used as a catalyst. The resulting product is recommended for lacquers, binding agents, or covering materials.

Tar oil (freed from pitch) is converted into a resin solution, by heating it with 1 per cent of concentrated sulphuric acid.<sup>100</sup> This solution can be used directly as a varnish or paint, or it can be mixed with other resins, asphalt, linseed oil or pigments.

Resinous bases were obtained by Wirth<sup>101</sup> from coal-tar and other tar oils boiling above 300°C. The tar, previously freed from phenols, is treated with caustic soda. The aqueous solution is separated, and the remaining material is treated with dilute sulphuric acid (sp. gr. 1.12). After removal of sulphates, the mixture is cooled and the resin is separated from the tar and washed with water.

The phenols from a low-temperature tar have been made to yield a resinous product by subjecting them to a cracking process, subsequently fractionating the end-products and polymerizing the appropriate fraction.<sup>102</sup> The material obtained is a yellow, hard resin.

It has often been observed that the wash-oil used in benzol-recovery plants has a tendency to thicken. Kattwinkel<sup>103</sup> attributed this thickening to the polymerization of unsaturated compounds under the influence of heat and of sulphuric acid, the latter being formed by the oxidation of hydrogen sulphide by air in the wash oil. Offe<sup>104</sup> disagreed with this explanation, stating that the thickening is caused by the combination of hydrogen sulphide with unsaturated constituents of the wash oil. By adding paraffin oil, benzol or light petroleum to spent wash-oil a thick pitch is obtained, containing 6-11 per cent sulphur.<sup>105</sup>

## Chapter 7

### Applications of Cumarone Resins

Cumarone resin<sup>1</sup> is employed for a variety of purposes, particularly in the manufacture of varnishes, printing inks, waterproofing materials, rubber compositions, floor tiles and chewing gum. Although its application is in certain measure restricted, the field of utility of this resin is being continually extended. The production of cumarone in the United States has usually been in excess of demand. The resin was utilized in Germany during the War to replace natural resins to a great extent<sup>2</sup> but since that time its use and production have diminished considerably. Manufacturers have striven to produce a material having a high melting point and as little color as possible and have been so successful in their efforts that the modern product is very uniform in quality and competes in a limited way with rosin ester in the preparation of varnishes.<sup>3</sup>

#### COMMERCIAL CUMARONE RESIN

Cumarone resin is a technical product of uniform properties. The highest grade resin is sold as a clear solid (in lumps or flakes) melting above 130°C. and having a pale amber color. The material is classified according to its melting (or softening) point, and in order to obtain lower grade products of a standard quality some manufacturers prefer to "cut back" a high-grade resin by the addition of softening agents.

**Grading.** In the United States, five different grades of cumarone resin are recognized as follows:

Rubber Grade S . . .	Melting point 50°-65°C.
Medium Soft . . .	Melting point 65°-85°C.
Rubber Grade H . . .	Melting point 85°-100°C.
Medium Hard . . .	Melting point 100°-135°C.
Varnish Grade . . .	Melting point 135°-160°C.

Besides the above grades, one company produces a hard and high-melting resin recommended for use in the manufacture of wax mixtures, quick-drying varnishes, and insulating compositions. This material, which is called "Indene resin," is said to consist essentially of polymerized indene. It has a melting point of 150-160°C.<sup>4</sup>

The color of cumarone resin, which is of importance in many of its applications, has been greatly improved with the development of the technic of manufacture so that most modern grades of resin are clear and of pale color, comparable with N rosin.<sup>5</sup> The color of the resin is usually compared arbitrarily with the color of the various grades of rosin.

<sup>1</sup> One brand of cumarone resin on the market is sold as "Cumar."

<sup>2</sup> W. Fahrion, *Chem. Umschau*, 1922, 29, 103, 111, 120; *Chem. Abs.*, 1922, 16, 2419. E. Glaser, *Brennstoff-Chem.*, 1921, 2, 99, 113; *Chem. Abs.*, 1921, 15, 2362.

<sup>3</sup> Technical applications of cumarone resin are reviewed by M. Brequet, *Industrie Chimique*, Feb. 1929; *Bull. federation ind. chim. Belg.*, 1929, 8, 272. T. H. Barry, *Ind. Chemist*, 1927, 3, 479; *Chem. Abs.*, 1928, 22, 878. J. Scheiber, *Farbe u. Lack*, 1931, 170; *Chem. Abs.*, 1931, 25, 3501.

<sup>4</sup> In other respects this "Indene Resin" is very similar to the mixed cumarone-indene resins.

<sup>5</sup> The resin is obtained in flake form by spreading in a thin layer on a cooling roll and removing with a scraper; S. P. Miller, U. S. P. 1,431,676, Oct. 10, 1922; *Chem. Abs.*, 1922, 16, 4258.

In Germany<sup>6</sup> the softening point of cumarone resin is used as a criterion for grading the resin according to the following classification:

Hard and brittle	Softening above 50° C
Hard	Softening between 40° and 50° C
Medium hard	Softening between 30° and 40° C
Soft	500 or more seconds for nail test <sup>7</sup>
Viscous	100 to 500 seconds for nail test
Liquid	Less than 100 seconds for nail test.

The last two classes, strictly speaking, are resins of the synthetic balsam type and are included because of their source of supply. Each of the above classes is sub-divided according to the color of the resin into five different grades, namely, light, light-brown, brown, dark-brown and black. The standard used for grading the color of the resins is a solution containing 1.5 grams of potassium dichromate in 100 cc. of 50 per cent sulphuric acid. Comparison is made against a solution of the resin in benzene, using a colorimeter or standard tubes and viewing a cross section of the liquids with the sky as a background. The color is graded as follows:

Light	When a 10 per cent solution is not darker than the standard.
Light Brown	When a 3.5 per cent solution is not darker than the standard.
Brown	When light shows through a 10 per cent solution.
Dark Brown	When light shows through a 5-10 per cent solution.
Black	When light does not show through the solution <sup>8</sup>

**Hardness.** According to Marcusson,<sup>9</sup> the hardness of cumarone resin is inversely proportional to the amount of resin soluble in an ether-alcohol mixture. That is, very hard resins contain substances soluble in an ether-alcohol mixture to the extent of 47 to 48 per cent, hard resins contain 56 to 58 per cent of soluble material, medium hard resins contain 66 to 68 per cent, soft resins contain 70 to 85 per cent, and fluid products contain 93 to 95 per cent of soluble substances. Glaser<sup>10</sup> also stated that the most desirable resins are those having from 40 to 50 per cent of material soluble in ether-alcohol solution. Modern, high-grade resins include very little material soluble in alcohol.

**Solubility of Cumarone Resin.** Cumarone resins are soluble in a large number of organic solvents,<sup>11</sup> benzene, toluene, solvent naphtha and turpentine being the best.<sup>12</sup> The solubility varies somewhat with the melting point of the resin, lower-melting resins being rather more soluble than resins of higher melting point. Cumarone resin is also soluble in ethyl acetate, amyl acetate, acetone, butyl oxalate, butyl acetate, carbon bisulphide, carbon tetrachloride, trichloroethylene, ethyl abietate, tricresyl phosphate, and all the ethers of ethylene glycol except the methyl ether.<sup>13</sup> It is partly soluble in varnish makers' and painters' naphtha and gasoline, and entirely so if a small proportion of benzene, acetone, or butylglycol- $\beta$ -ethyl ether is added.<sup>14</sup> It is also partially dissolved by diacetone

<sup>6</sup> E. Glaser, *Brennstoff-Chem.*, 1921, 2, 113; *Chem. Abs.*, 1921, 15, 2362

<sup>7</sup> The "nail test" is designated as the time required for a 130 mm wire nail (23-24 g.) to sink from point to head at 20°C. J. Marcusson, *Chem.-Ztg.*, 1919, 43, 109, 122; *Chem. Abs.*, 1919, 13, 2607

<sup>8</sup> The last three grades are determined by viewing the benzene solution of the resin in a tube 15 mm. in diameter. The tubes are placed in a box with appropriate apertures and viewed against a 50 candlepower light.

<sup>9</sup> J. Marcusson, *Chem.-Ztg.*, 1919, 43, 109, 122; *Chem. Abs.*, 1919, 13, 2607.

<sup>12</sup> A. Eichler, U. S. P. 1,133,432, Mar 30 1915; *Chem. Abs.*, 1915, 9, 1398.

<sup>13</sup> It is also soluble in 1,4-dioxane. E. W. Reid and H. E. Hofman, *Ind. Eng. Chem.*, 1929, 21, 695

<sup>14</sup> French P. 771,863, 1934, to Alexander Wacker Ges für elektrochem. Ind. G.m.b.H.; *Chem. Abs.*, 1935, 29, 1537.

alcohol, ethyl lactate and ethyl phthalate. Petroleum distillates (particularly those derived from asphaltic base) boiling between about 155 and 210°C. exert a considerable solvent action, but the resin is less soluble in light petroleum benzines or in higher-boiling fractions. The softer grades of cumarone resin blend with paraffin oil in amounts up to 50 per cent; the harder grades blend in mixtures containing less than 5 per cent or more than 80 per cent of paraffin oil to give clear solutions. Most of the vegetable and animal oils, including menhaden oil, perilla oil, rapeseed oil, tung oil, linseed oil and soya bean oil, also pine oil and rosin oil, are solvents for cumarone resin in all proportions. The resin is less soluble in bodied oils and still less so in blown oils. It is miscible in all proportions in stearic acid, ozokerite, gilsonite, Japan wax, carnauba wax, and beeswax. In ceresin wax, and in hard paraffin wax, however, cumarone resin is only partially miscible, and it is not soluble in low-melting paraffin wax.

Cumarone resin is practically insoluble in methyl, ethyl, or amyl alcohols, or in butyl phthalate, castor oil, and diethylene glycol. Certain modified cumarone resins (prepared by the action of sulphuric acid on solvent naphthas containing phenols as well as cumarone and indene),<sup>15</sup> soluble in ethyl and similar alcohols have, however, been described.

Solutions of cumarone resin are considerably more viscous than the corresponding ones of rosin and rosin ester. To obtain solutions of similar viscosity it is necessary to use approximately 1.7 times the amount of solvent required for the preparation of rosin or rosin ester solutions of corresponding viscosity.

**General Chemical Characteristics.** Cumarone resin is distinguished from many natural and some synthetic resins by the fact that it is quite neutral and almost completely non-saponifiable. It appears to possess some unsaturation, and iodine numbers of 38 to 43.5 have been obtained with resins from one source. Objectionable impurities, such as sodium sulphate, sodium sulphonates, and free sulphonic acids are sometimes present but the best-grade products contain such materials in very minute quantities. The resin is unaffected by water, most acids, alkalis or salts and is fairly resistant to oxidation. On heating to temperatures above about 300°C., however, it undergoes partial depolymerization.

#### CUMARONE RESIN IN VARNISH MAKING

The application of cumarone resin in the form of a solution as a protective coating for wood and metal was first suggested by Kraemer and Spilker.<sup>16</sup> Since then a number of variations in the solvents employed and in the purposes for which the solution is to be used have been proposed. Cumarone resin is used to some extent in the preparation of oil varnishes such as floor, spar or rubbing varnishes, particularly in conjunction with linseed oil and tung oil. When properly made the resulting varnishes are equal for some purposes to those made from ester gum and certain of the fossil resins. Kappelmeier<sup>17</sup> points out, however, that the low durability and elasticity of cumarone resin films is a decided drawback.

Cumarone resin, used with a solvent has also been suggested as a substitute for linseed oil in varnishes.<sup>18</sup> According to Emery,<sup>19</sup> the neutral character of the resin is a disadvantage in using it alone as a varnish resin and the most satisfactory varnishes of the kind are made on the basis of 50 per cent rosin and 50

<sup>15</sup> German P. 302,543, 1917, to Rütgerswerke A.-G.; *J.S.C.I.*, 1920, 39, 307A. See Chapter 6.

<sup>16</sup> G. Kraemer and A. Spilker, *Ber.*, 1890, 23, 78; *J.S.C.*, 18'0, 58, 496.

<sup>17</sup> C. P. A. Kappelmeier, *Chem. Weekblad*, 1934, 31, 423.

<sup>19</sup> R. L. Emery, *Paint, Oil, Chem. Rev.*, 1929, 87 (3), 9, 21. R. S. Green, *Amer. Paint J.*, 1930, 14 (15), 20; *Paint, Oil, Chem. Rev.*, 1930, 89 (5), 11; *Chem. Abs.*, 1930, 24, 1234. W. W. King, *Paint, Oil, Chem. Rev.*, 1921, 72 (10); *Chem. Abs.*, 1921, 15, 3909.

per cent cumarone resin. The chief objection is the tendency to form a darker-colored product. A varnish which dries to a hard film in 3 to 4 hours can be obtained by adding rosin to China wood oil at 296°C., and cumarone resin at 232°C., together with driers consisting of 0.06 to 0.12 per cent of cobalt acetate and 1 per cent of lead oxide based on the weight of oil used.

In the preparation of "long oil" varnishes with tung oil it is usually necessary to add a moderate quantity of rosin as well as cumarone resin since the latter does not exert as great a solvent action on the polymerized oil as the rosin. Furthermore, it has been reported that the rate of oxidation of tung oil is much slower in cases where the oil is bodied with cumarone resin alone.<sup>20</sup> According to Kenny<sup>21</sup> cumarone resin is just as effective as limed resin in retarding the gelation of tung oil. Rapid-drying varnishes yielding promising films were produced by Rhodes and Potts<sup>22</sup> by bodying tung oil in the presence of small amounts of glycerol (to retard gelation) and 0.02 per cent of lead linoleate. After heating at 280°C. until the oil was sufficiently thickened, the cumarone resin was added and the mixture thinned with turpentine. When using lead as a drier for varnishes containing cumarone resin it is best employed in the form of the resinates, as otherwise the lead is precipitated on standing, because of the low acidity of the composition. Buc<sup>23</sup> prepared a varnish containing from 50 to 90 per cent of linseed or tung oil, 5 to 25 per cent of resins (ester gum, cumarone resin or fossil resins) and 5 to 25 per cent of the calcium salt of an oil-soluble sulphonic acid of the kind produced by treatment of petroleum oil with fuming sulphuric acid. The varnish is thinned with turpentine. Addition of the latter substance is often necessary to prevent clouding of cumarone-resin varnishes having only small proportions of rosin derivatives.

According to King,<sup>24</sup> a high-grade varnish can be produced by heating a drying oil such as tung oil to about 470°F., adding cumarone resin, and heating to about 530° until the mixture has such a consistency that it will set when cold. Additional cumarone resin may be added while the mixture is hot and thinners are added on cooling. Typical formulas suggested by King are those given in Table 20

TABLE 20 —Cumarone Resin Varnishes

Formula	Short-Oil	Medium-Oil	Long-Oil
Tung oil. . . . .	100 pounds	125 pounds	150 pounds
Linseed oil . . . . .	—	18 pounds	75 pounds
Cobalt linoleate . . . . .	1 pound	1½ pounds	2½ pounds
Cumarone resin.. . . .	100 pounds	100 pounds	100 pounds
Thinner . . . . .	200 pounds	300 pounds	380 pounds
Natural resin*. . . . .	—	—	75 pounds

\* Vegetable resin i. e., rosin or copal.

Additional formulas for the preparation of various types of varnishes are given below. It should be understood, however, that in the manufacture of varnishes the character of the oils, driers and thinners employed must be taken into consideration, as well as the technic of the varnish maker. The formulas included here serve simply as a starting point and the precise quality, or combination of qualities, sought may demand special consideration in each case. With slight changes in the proportions of oil and variations in the temperature control, satisfactory compositions for many purposes can be made. In some cases the products prepared from cumarone resin exhibit a tendency to turn yellow on exposure

<sup>20</sup> F. H. Rhodes and T. T. Ling, *Ind. Eng. Chem.*, 1925, 17, 508.

<sup>21</sup> J. A. Kenny, *Am. Paint. J.*, 1930, 14 (12), 20; *Paint. Oil, Chem. Rev.*, 1930, 89 (2), 12; *Chem. Abs.*, 1930, 24, 1234. H. Hadert, *Farbe u. Lack*, 1928, 558; *Chem. Abs.*, 1929, 23, 721.

<sup>23</sup> H. E. Buc, U. S. P. 1,735,493, Nov. 12, 1929, to Standard Oil Development Co.; *Chem. Abs.*, 1930, 24, 739.

<sup>24</sup> W. W. King, U. S. P. 1,587,333, June 1, 1926, to Barrett Co.; *Chem. Abs.*, 1926, 20, 2410.

to the weather. Although this feature is not objectionable in many instances, it should be borne in mind when the manufacture of white enamels, or other light-colored shades, is contemplated. The tendency of the coatings to become yellow is accentuated by the action of light, an exposure of twenty-four hours serving to develop the maximum color. This discoloration, however, is only of minor degree and negligible in most applications.

**Spar Varnish.**<sup>25</sup> Long-oil or spar varnishes have been prepared using cumarone resin and as an example the following formula is given:

Twenty gallons of tung oil and 20 pounds of resin are heated to 280°C. and then drawn off the fire. When a test sample strings, 10 gallons of linseed oil are introduced to chill the mixture. One hundred pounds of cumarone resin are then added and the mixture heated to 266°C. and maintained at this temperature for 15 to 30 minutes. The batch is then cooled and 2.5 pounds of cobalt linoleate are added, followed by 40 gallons of a solvent such as turpentine, naphtha, benzene, or a mixture of these solvents. The use of such a comparatively large proportion of linseed oil is advantageous in that a more elastic varnish is obtained.

Another long-oil varnish which gives free-flowing coatings may be prepared by adding 26 pounds of ester gum and 44 pounds of hard cumarone resin to 38 gallons of tung oil at 205°C. The batch is heated so as to obtain a top temperature of about 290°C. in 30 minutes and as soon as the correct consistency is attained, 4 pounds of fused lead resinate and 26 pounds of cumarone resin are added. Sufficient bodied linseed oil (about 7 gallons) is introduced to cause the temperature to drop to about 250°C. The varnish is thinned with 72 gallons of mineral spirits. Liquid driers containing cobalt and manganese are added at 175°.

**Floor Varnish.** The following is a representative formula for the preparation of medium-oil or floor varnishes:

Cumarone resin . . . . .	100.0 pounds
Tung oil . . . . .	15 5 gallons
Linseed oil . . . . .	2 5 gallons
Cobalt linoleate . . . . .	1.5 pounds
Thinner . . . . .	34.0 gallons

The tung oil is heated to about 245°C and one-half to three-quarters of the cumarone resin is added while the mixture is still on the fire, with sufficient stirring to prevent the resin from sticking to the bottom and sides of the kettle with consequent darkening of the varnish. The temperature is raised to 280°-293°C. and the kettle contents maintained at this temperature for 15 to 30 minutes or until a drop on a cold glass sets to a fairly hard button (the mixture should, however, not string). The remainder of the cumarone resin and all the linseed oil are added with stirring to check the heat. The mixture is allowed to cool and the thinner and drier added. The resulting varnish is reported to be quick-drying, tough, resistant to acids and alkalies and is waterproof.

Varnishes prepared at temperatures of about 280°C. sometimes show a slight bloom. In such cases it is better to work at somewhat higher temperatures, about 295°. The resulting products are slightly darker than those obtained at the lower temperature but the waterproofing qualities are said to offset this disadvantage. It should be borne in mind that cumarone resin darkens rapidly above 280°C. and it is therefore necessary to "body" the oil as much as possible before the resin is added in order to avoid exposure to a high temperature for too long a period. If the varnishes are made at 260°C., the resin has a tendency to fall out. On the other hand, if heating is carried above 300°C., the resulting material will be considerably darker than varnishes properly prepared from the usual natural resins.

<sup>25</sup> Typical varnish formulas in which cumarone resin is employed have been described by J. A. Kenny, *Am. Paint J.*, 1930, 14 (12), 20, 22, 24, 26; *Paint, Oil, Chem. Rev.*, 1930, 89 (2), 12; *Chem. Abs.*, 1930, 24, 1234; R. S. Green, *Am. Paint J.*, 1930, 14 (15), 20, 22, 24, 26; *Paint, Oil, Chem. Rev.*, 1930, 89 (5), 11; *Chem. Abs.*, 1930, 24, 1234; and E. E. Walker, *Times Trade and Eng. Suppl.*, 1931, 28 (664), 7; *Chem. Abs.*, 1931, 25, 2863.

**Short-Oil Varnish.** The following formula may be used for short-oil or rubbing varnishes:

Cumarone resin . . . . .	100 pounds
Tung oil . . . . .	12 gallons
Cobalt linoleate . . . . .	14 ounces
Thinner . . . . .	28 gallons

The procedure and preparation of this type of varnish is similar to that of medium-oil varnishes. The kettle is drawn from the fire and held until a sample, when cold, sets to a hard button. The resulting product has good flow and can be polished when dry without sweating.

Another formula for a short-oil varnish is as follows: Ten gallons of tung oil are heated to 204°C. and 30 pounds of cumarone resin added. The batch is heated to 290°C. and maintained at that temperature until a test shows that the desired consistency has been attained. Then 70 pounds more of cumarone resin are added to chill the mixture. As soon as the resin has completely dissolved, 25 gallons of mineral spirits are added and a liquid cobalt drier (0.10 per cent metal based on weight of oil) at 175°.

By mixing about 2 pounds of aluminum powder per gallon of a varnish prepared with cumarone resin as a constituent, fairly good waterproof coatings can be made. For interior work, a short-oil varnish of the type already described meets many requirements; however, for exterior application on steel tanks and structural steel, a long-oil varnish is of course more desirable.

Another application of cumarone resin in the varnish industry is its use as a modifying agent for oil-soluble resins of the phenol-formaldehyde type.<sup>26</sup>

Wrinkle-finish varnishes were made by Root<sup>27</sup> by use of Congo resin and blown linseed oil. Cumarone resin as a hardening agent in this type of finish was later described by Burgman.<sup>28</sup>

A representative composition may be prepared by adding a pigment (5 lb.), japan drier (3 gal.), cumarone varnish (6 gal.) and benzene (10 gal.) to a varnish base (40 gal.) comprising tung oil, 5 to 10 per cent of rosin based on the weight of oil, and cooled with the weight equivalent of high-flash naphtha. The composition is applied and subsequently baked.

**Lacquers.** Cumarone resin is not compatible with nitrocellulose and cannot be used in lacquers as the sole resin.<sup>29</sup> However, if a mutually tolerant resin is also present, the cumarone blends and a clear film is produced on drying. According to Rogers and Banta,<sup>30</sup> a ratio of 7 parts of ester gum to 4 parts of cumarone resin produces a durable lacquer.<sup>31</sup> A typical formula contains the following ingredients expressed in per cent by weight:<sup>32</sup>

Nitrocellulose ( $\frac{1}{2}$ sec., wet with 30 per cent of alcohol) . . . . .	8
Butanol . . . . .	10
Toluene . . . . .	31
Ethyl acetate . . . . .	10

<sup>29</sup> A. Jones (*Ind. Finishing*, 1932, 3, 156; *Chem. Abs.*, 1932, 26, 5775) has discussed cumarone lacquers.

<sup>30</sup> A. Rogers and C. Banta, *Ind. Eng. Chem.*, 1928, 20, 198. A. Rogers, U. S. P. 1,884,225, Oct. 25, 1932, to Barrett Co.; *Chem. Abs.*, 1933, 27, 1219.

<sup>31</sup> The durability of colored lacquers containing various synthetic and natural resins has been investigated by H. A. Gardner, *Tech. Circ., U. S. Paint Mfrs' Assoc.*, 1925, 252, 168; *Chem. Abs.*, 1926, 20, 1145.

<sup>32</sup> R. L. Emery (*Paint, Oil, Chem. Rev.*, 1929, 87 (3), 9, 21) has advocated the use of xylene instead of toluene in the preparation of cumarone resin lacquers.

The cotton is placed in a convenient container for mixing, and butanol and toluene added. When thoroughly wetted, ethyl acetate, butyl acetate and dibutyl phthalate are introduced and the mass is stirred until dissolved. The mixture of ester gum and cumarone resin is now added and dissolved by continued stirring.

Cotton<sup>33</sup> stated that cumarone resin gives lacquers which tend to blush but that this tendency is eliminated by its partial replacement by gutta-percha resin.

Coating compositions and plastic products from cellulose esters are said to be improved by the addition of small quantities of cumarone resin.<sup>34</sup> Lacquers have also been suggested from cellulose derivatives such as acetylcellulose using cumarone resin and various solvents.

Solutions of cumarone resin have been recommended as components in the preparation of bronzing liquids.<sup>35</sup> The addition of a small quantity of stearic acid to such solutions has also been proposed.<sup>36</sup>

As a substitute for pyroxylin lacquers, Kessler<sup>37</sup> proposed to employ cumarone resin softened by tung oil, using as solvents mixtures of benzene and xylene, alcohol and fusel oil, or a mixture of all these thinners.

**Other Coating Compositions.** A composition for coating nails is stated<sup>38</sup> to consist of a resin of the cumarone type, melting at 105-110°C., mixed while in the molten condition with 30 per cent by weight of benzol. Lacquers said to be of value as ships' paints are prepared by Plauson<sup>39</sup> by the addition of cumarone resin, or hardened resin, to a dispersion of vulcanized rubber or balata in a low boiling saturated or chlorinated hydrocarbon solvent. The mixture is subsequently colloidized by heating to 180°C. Mention is made by Bowles<sup>40</sup> of the utilization of cumarone resin in antifouling paints, particularly for ships' plates. It is reported, however, that protective paints, made from cumarone resins, exhibit a tendency to crumble away when exposed to sea-water.<sup>41</sup>

Blass<sup>42</sup> polymerized the cumarone and indene in solvent naphtha with sulphuric acid and neutralized the free acid with dry alkalies. The resulting solution is used directly as a paint base. He suggests Portland cement as a pigment.

An application of cumarone resin is in the manufacture of an enamel or paint for coating the interior of containers used in canned foods (particularly corn). Tin-plate containers are frequently attacked with the formation of dark-colored, objectionable compounds; this discoloration is inhibited by application of one of the following mixtures:

(1) Cumarone resin, 10 parts, and zinc oxide, 5 parts.

(2) Cumarone resin, 18 parts, gutta-percha 4 parts, and zinc oxide, 11 parts.

(3) Cumarone resin, 18 parts, chicle gum, 4 parts, and zinc oxide, 11 parts.

In making up the compositions, the cumarone resin, chicle gum, and gutta-percha are dissolved in about 5 parts by weight of carbon tetrachloride and zinc oxide is stirred in. After the mixture has been passed twice through a paint mill, sufficient carbon tetrachloride is added to reduce the total solids to about 5 per cent. This composition is applied to the cans and baked.<sup>43</sup>

Steigerwalt<sup>44</sup> has reported that cumarone resin is apparently unaffected by immersion in acetic or lactic acid. On the basis of such tests he suggested that the resin, in conjunction with emulsified asphalts, rubber or Portland cement, be employed as a coating for silos.

Solutions of cumarone resin have been used for a wide variety of purposes, particularly for the production of waterproofing compositions and adhesive mixtures. A dilute solution of the resin in benzene or toluene containing an oil-soluble dye has been recommended for tinting cloth exposed to the weather, such as the lining of automobile tops.<sup>45</sup> Chabert<sup>46</sup> impregnated textile fibers by dipping them into a bath containing cumarone resin, hydrogenated fish oil, a solvent of the type of mineral spirit, and acetone. A waterproofing composition for use on leather, canvas, or other fabric, and also for rust-proofing metal, was prepared by Shaffer<sup>47</sup> by mixing a solution of cumarone resin (preferably of high melting point) in high-flash naphtha, with one of paraffin wax and rubber cement in gasoline. According to Crawford,<sup>48</sup> 50 parts of cumarone resin and 40 parts of carnauba wax incorporated with 20 parts of linseed oil at 177-204°C. with constant agitation for 45 minutes gives a preparation for coating electrical coils. Compositions containing the resin for the waterproofing of leather<sup>49</sup> and paper<sup>50</sup> have also been described. In the case of leather, paraffin wax is mixed with 5-30 per cent of rubber or gutta-percha and a small amount of cumarone resin. Application is made at 95°C. Waterproof paper is manufactured in such a way that the resin along with menhaden oil is distributed between the fibers.

The unsaponifiable nature of cumarone resin has led to its employment in solvents or compositions for waterproofing cement floors and in the manufacture of cement binders.<sup>51</sup> Water-immersion tests on concrete panels coated with a cumarone resin varnish and then painted with chrome green showed the varnish to be outstanding in its preventing attack of Prussian blue in the paint.<sup>52</sup>

Fleischmann<sup>53</sup> obtained a waterproof floor-covering cement by dissolving one part by weight of a high-melting cumarone resin in about 0.25 to 2 parts of benzol and incorporating from 0.5 to 4 parts of a clay filler. Still another use has been proposed by McCoy,<sup>54</sup> who impregnated molded articles made of Portland cement or asbestos with a solution of cumarone resin to render them more adaptable for use in the manufacture of electrical apparatus. The articles are then baked.

Ellis<sup>55</sup> prepared a quick-drying paint, which dries to a flat or dull finish and can be applied to wall plaster or other surfaces to produce a flat waterproof finish, by dissolving cumarone resin of melting point about 90°C. in a mixture of about 9 parts of gasoline and 1 part of toluene and incorporating a pigment such as lithopone, iron oxide, ochre or Brunswick green.

Sprenger<sup>56</sup> prepared a varnish by treating (for 1 hour) oils containing cumarone and indene (to which had been added 5-10 per cent of animal or vegetable oil) with 21 per cent of concentrated sulphuric acid. The temperature was kept below 50°C. Freshly slaked lime was then added to neutralize sulphuric acid and combine with any free fatty acids. After removal of insoluble calcium salts, the varnish oil obtained was of a clear brownish-yellow color and, when applied in a thin film, dried to an elastic coating. Lender and Koch<sup>57</sup> made a varnish base by adding drying oils, natural resins or animal and vegetable waxes to a solution of cumarone-indene resin in solvent naphtha and subsequently evaporating the solvent. Another base was secured by heating tung oil to 220-240° and incorporating an equal weight of cumarone resin. For the manufacture of varnishes, Eichler<sup>58</sup> recommended the addition of linseed, poppy seed, cottonseed or soya-bean oils, in small quantities at a time, to cumarone resin heated to about 160°C. By combining heat-polymerized cumarone resin with oils such as corn oil, soya-bean oil and tung oil, Darrin<sup>59</sup> obtained a composition possessing electrical insulating properties. Edison<sup>60</sup> used a solution of the resin to coat electrodes of electroplating cells to prevent deposition of metals. Dayol<sup>61</sup> suggested a vehicle for paints consisting of a mixture of 60 per cent of cumarone resin, 40 per cent of xylene and a small amount of drier and oil of mirbane. A coating, prepared by Holzapfel,<sup>62</sup> consisted of cumarone resin and 1 to 10 per cent of rubber. Stearin pitch may also be incorporated in some cases.

Stewart<sup>63</sup> made a varnish by treating an unsaturated vegetable oil, such as tung oil, with a small proportion of phosphorus pentoxide. A gelatinous material is formed by polymerization and the mixture is immediately added to a solution of cumarone resin in linseed oil. Polymerization is completed by heating and allowing the mixture to stand. The products are said to have weather-resisting properties. Schmidding<sup>64</sup> described the preparation of lacquers by the addition of cumarone resin to tung oil which has been thickened without gelatinization (by rapid heating to 280-300°C.). Another procedure<sup>65</sup> consists in dissolving coal-tar or water-gas tar pitch in solvent naphtha and subsequently polymerizing the resins by blowing in steam at 160° or by the aid of catalysts. Lender<sup>66</sup> prepared a varnish base by heating cumarone resin (oils may be added to modify the product) with sulphur or sulphur chloride<sup>67</sup> under pressure. Schwarz<sup>68</sup> stated that a liquid applicable for use as a varnish was produced by treating hot cumarone resin with air or oxygen<sup>69</sup> under pressure and emulsifying the product with water, using glue and potassium bichromate to stabilize the emulsion. A varnish-base can be produced by heating a phenol-aldehyde resin with cumarone resin and

wood-oil.<sup>70</sup> Such mixtures are prepared for application as varnishes or impregnating agents.<sup>71</sup>

A bituminous paint containing cumarone resin is produced by heating coal-tar pitch to 160-200°C., cooling the pitch to 150° and then adding a solvent containing the resin, or a solution of cumarone and indene which afterwards is polymerized by heating in an autoclave.<sup>72</sup>

Briggs<sup>73</sup> described an enamel consisting of cumarone resin, a pigment and an oil. This material was stated to be applicable for use as a top coating on slow-drying paints or varnishes. An elastic, waterproof coating composition (containing cumarone resin as one ingredient) intended as a surfacing compound on brick, stone or iron was prepared by Robeson.<sup>74</sup> This material consists of the resin, a mineral or vegetable wax, a solvent, a pigment and silicon carbide.

#### USES OF CUMARONE RESIN IN RUBBER COMPOSITIONS

Among the various applications of cumarone resin, its use in the manufacture of rubber goods is second to its employment in varnish making. The resin exerts a pronounced softening effect upon rubber during milling, and the addition of a small quantity (usually about 5 per cent), in either powdered or molten form, facilitates handling of the rubber batch on the rolls.<sup>75</sup> The adhesive properties of friction tape are increased by incorporation of cumarone resin. It is also a plasticizer for tire treads, sidewalls and friction stocks, helps to produce a smooth-running tube stock, and is said not to affect aging qualities. The resin may be used in making tiling, matting, hose, heels and various other types of mechanical rubber goods. Mixed with stearic acid and paraffin, it forms a flux which not only plasticizes the gum but gives the vulcanized product a glossy surface.<sup>76</sup> It can also be employed with advantage in rubber cements and gutta-percha compositions and as a softener for reclaimed rubber.<sup>77</sup> The softening action of cumarone resin may be illustrated by its proposed use in the preparation of a latex substitute.<sup>78</sup> Thus, plasticization of the rubber is accomplished with the aid of the resin and the resulting product is masticated with a stiff paste of a water-soluble organic colloid (e.g., rosin soap) containing an attriting agent.

On the other hand, it is stated<sup>79</sup> that cumarone resin is less beneficial in the curing of rubber with zinc oxide than are some of the more acidic resins (e.g., rosin or pine tar) which exert an increase in the tensile strength of rubber up to 2 per cent. This effect is probably due to the increased solubility of the zinc oxide in the presence of acids. Cumarone resin being neutral in character can have no such solvent action.

<sup>75</sup> J. Y. Malone (U. S. P. 1,990,996, Feb. 12, 1935; *Chem. Abs.*, 1935, 29, 2262) incorporated cumarone resin with rubber after it had been milled and aged to prepare an adhesive for glass or celluloid.

<sup>76</sup> J. J. O'Hare, U. S. P. 1,985,261, Dec. 25, 1934, to Am. Hard Rubber Prod. Corp.; *Chem. Abs.*, 1935, 29, 1284.

<sup>77</sup> H. McGee (British P. 389,873, 1931, to Improved Textile Rollers, Ltd.; *Brit. Chem. Abs.*, B, 1932, 481) reclaimed rubber by mixing the disintegrated material with cumarone oil and vulcanizing agents. The resulting mass is then molded under heat and pressure.

<sup>78</sup> H. L. Levin, U. S. P. 1,950,451, Mar. 13, 1934, to Patent & Licensing Corp.; *Chem. Abs.*, 1934, 28, 8270.

<sup>79</sup> W. F. Russell, *Ind. Eng. Chem.*, 1929, 21, 737.

According to Miller,<sup>80</sup> cumarone resin is improved for rubber-compounding purposes and the tendency to "bloom" is reduced by mixing 10-20 per cent sulphur in the molten resin. Richards and Smith<sup>81</sup> advocate the employment of the resin in the reclaiming and dispersing of vulcanized rubber.

Wells<sup>82</sup> prepared a product for making gaskets by mixing the resin with rubber and fillers, such as clay or asbestos. The material so obtained was subsequently shaped and vulcanized.

McCoy<sup>83</sup> made a cement (for sealing vacuum apparatus) by heating a mixture of 10 to 50 per cent of gutta-percha, 50 to 80 per cent of cumarone resin, and a filler such as precipitated chalk to a temperature of about 260°C. The cements may be repeatedly melted and solidified without impairing their properties and are exceedingly tough.

Rubber cements proposed as surfacing material for floors or roads, or as acid-resisting coatings, are made by mixing cumarone resin and a water-setting cement (e.g., Portland cement) with a dispersion of an aqueous liquid in rubber and allowing the composition to set. The resin counteracts any retarding effect of rubber solvent on the setting.<sup>84</sup>

An adhesive consisting of 2-5 parts of Karaya gum, 25 parts of cumarone resin, 17 parts of spindle oil and 100 parts of rubber latex (containing 33 per cent of solids) has been described.<sup>85</sup> Teague<sup>86</sup> mixed an emulsion of cumarone resin in water with rubber latex in the presence of thickening and stabilizing agents. It is stated that the best results are obtained with a resin melting at 40°C. Another procedure<sup>87</sup> consists in blending an emulsified mixture of cumarone resin and neutralized pine tar with an aqueous dispersion of rubber.

By kneading together at 140°C. 100 parts of cumarone resin and 15 parts or less of vulcanized rubber (in crumb form), Blumberg<sup>88</sup> secured a plastic material applicable for cementing and insulating purposes. The use of solvents during mixing and replacement of the cured rubber with crude or chlorinated rubber were suggested. Drew<sup>89</sup> mixed plasticized rubber (clear crepe or smoked sheets), cumarone resin and pigments such as zinc oxide. The resulting mixture is incorporated with benzene or gasoline. It may be used on paper or other material.

Paulitsch<sup>90</sup> used a preparation containing cumarone resin (40 parts), ethyl alcohol (50 parts) and potassium carbonate (10 parts) as a coating for tires and footwear.

A composition proposed by Miller<sup>91</sup> may be prepared by dissolving about 8 per cent by weight of crude unvulcanized rubber in molten cumarone resin of melting point between 125°C. and 128°. The resulting product melts at about 123° and may be used in varnishes, paints, lacquers, enamels, insulating compounds, waterproofing materials for fibrous materials and in the manufacture of linoleum.

A blend of oily distillates and still residues from coal tar has been recommended

for use in rubber compositions. The addition of 2 per cent to the gum during milling aids in dispersion of fillers.<sup>92</sup> Similar use is made of mixtures of cumarone resin and coal-tar oils.<sup>94</sup>

**Chicle Substitutes.** As cumarone resin mixes with chicle, pontianak rubber, rubber resin and flavoring oils, and can be obtained free from oily substances which impart a disagreeable flavor, it has been suggested as an ingredient for chewing gum.<sup>94</sup> Generally about 7-10 per cent of the resin is incorporated with chicle. Although slight changes in the manufacture of cumarone resin have resulted in the exudation of sweetening material when it is employed as a chicle substitute, this difficulty can be overcome by careful selection of the grade of resin.

A chewing gum base material may be prepared by drying (at above 100°C.) a mixture of rubber latex, powdered cumarone resin, and hard hydrogenated oil in a mixer, kneading at 115° to 120° and adding cacao powder or other filling material.<sup>95</sup> Another method is to cream rubber latex with a solution of caustic soda, and mix the upper cream layer with cumarone resin. The mixture is heated and stirred, then the alkali is removed by washing. The residual water is evaporated and the product is blended with hard hydrogenated oil.<sup>96</sup>

#### MOLDED ARTICLES

Cumarone resin has found only a limited application in the preparation of molded articles because it is too brittle and possesses a low tensile strength. Its incorporation has been suggested in the so-called cold-molded products when mixed with other materials such as asphalt, petroleum pitch or gilsonite. Cumarone resin has found but slight application in the manufacture of hot-molded articles.<sup>97</sup> As contrasted with its disadvantages, cumarone resin possesses the property of being resistant to moisture and climatic conditions, besides possessing excellent insulating characteristics. Porcelain and gutta-percha are examples of materials possessing higher dielectric constants. Table 21 gives comparative values of the dielectric constants of cumarone resin and various other materials, measured under the same conditions.

TABLE 21.—*Dielectric Constants of Various Insulating Materials*

Substance	Dielectric Constant
Porcelain . . . . .	5.73
Gutta-percha . . . . .	4.0 to 4.9
Cumarone resin . . . . .	3.5
Shellac . . . . .	3.10
Vulcanized rubber . . . . .	2.69
Rosin . . . . .	2.5
Rubber . . . . .	2.12

The addition of cumarone resin to products made by reacting phenols with formaldehyde was proposed by Baekeland.<sup>98</sup> Resinous substances such as polymerized cumarone and indene, when mixed with Bakelite, not only control the rate

<sup>97</sup> Cumarone has been used in thermoplastic molding compositions made from hardened shellac; W. A. Broughton, U. S. P. 1,953,951, Apr. 10, 1934, to New England Mica Co.; *Chem. Abs.*, 1934, 28, 3920. See also Chap. 37.

<sup>98</sup> L. H. Baekeland, U. S. P. 1,033,475, Sept. 10, 1912; *Chem. Abs.*, 1912, 6, 2534.

of hardening, but also facilitate molding.<sup>100</sup> In the preparation of molded articles from filler stock of asbestos, silica and wood flour, McCoy<sup>100</sup> used the resin as a binder in addition to polymerized vegetable oils, such as tung oil, or sterculia oil. The molding composition was preshaped to the desired form and then, by means of heat and pressure, formed into the finished molded article. The operation could also be carried out by the cold-molding process, but in this case less vegetable oil must be used in the composition. When shaped in the latter way, the articles are finally subjected to a baking treatment<sup>101</sup> in order to polymerize the binder.<sup>102</sup> The molded products have adequate insulating power. For cold molding, a recommended mixture consists of 70 parts of asbestos, 30 parts of cumarone resin and 1 to 2 parts of tung oil.

Wells<sup>103</sup> prepared an insulating composition by dissolving cumarone resin in a solvent such as benzene, admixing with asbestos, drying, heating, and molding the material under high pressure. The proportion of cumarone resin may be varied within wide limits, depending upon the physical qualities desired, and shellac, asphalt, or other resins may be incorporated.

By grinding a mixture of cumarone resin and filling material with water, Gudge<sup>104</sup> found that some of the difficulties encountered in using resinous binders for the preparation of molded articles could be overcome. Without the use of water, the resin sometimes "balls" with the filler or, if a ball mill is employed, the mix adheres to the sides of the mill so that mixing is not uniform.

Cumarone resin, mixed with shellac<sup>105</sup> or phenol-formaldehyde resin,<sup>106</sup> is suggested as a bonding agent for abrasive granules. The binder may be incorporated with the granules in the presence of a solvent (e.g., furfural) and the article baked.

Groten<sup>107</sup> obtained an insulating composition for use in the construction of coils and condensers for motor ignition systems by heating a mixture of 85 per cent of cumarone resin (melting at 80-100°C.) with 15 per cent of tung oil at 130° until a clear liquid results. This material, which has a melting point of about 60°, forms a permanent insulation. Magnetic cores of high permeability are produced by impregnating a metallic powder with liquid or soft cumarone resin along with asphalt and pitches.<sup>108</sup> The preparation is molded by subjecting it to pressure.

Brown<sup>109</sup> suggests adding 10-35 per cent of cumarone resin to tung oil and heating at 200-250°C. until the mixture is of the requisite body. This is applied, either directly or in solution, to fabrics which, after drying by baking, are rendered waterproof and electrically insulated. Products said to be useful as adhesive plasters and as impregnating agents have been prepared from equal parts of naphthol pitch, sesame oil and cumarone resin.<sup>110</sup>

Grant and Farren<sup>111</sup> proposed a mixture of molten cumarone resin, molten

sulphur and a filler of sand, clay, glass or brick dust as a waterproof and dielectric sealing material for electrical blasting caps and other protective containers for delicate electrical and mechanical units. A mixture of sulphur and a soft cumarone resin is cold molded by Herbst and Endriz<sup>112</sup> and then baked for about 16 hours at 250-260°C. to secure hard black articles reported to have high dielectric strength.

Electrically insulated compositions for the construction of partitions are made by mixing a solution of nitrocellulose, cumarone resin, shellac, copal, and tricresyl phosphate in solvents with slag wool or asbestos, and evaporating the volatile constituents.<sup>113</sup> A sound- and shock-insulating medium is composed of a vulcanized oil mixed with magnesium oxide and cumarone resin.<sup>114</sup> Textile webbing impregnated with cumarone resin was proposed by Haas<sup>115</sup> for molding into a water-lubricated bearing.

On account of its resistance to saponification cumarone resin has been proposed as a binding agent for constructional materials. Reumann<sup>116</sup> produced a composition for building and road-making purposes by adding to molten cumarone resin pieces of marble, lithopone, hard waxes and rubber. Plauson<sup>117</sup> employed cumarone resin as a dispersing agent for the hard pitch, bitumen or natural resin which are added to the tar. The resin is manufactured *in situ* by heating a mixture of tar, solvent naphtha and sulphuric acid. Another procedure involves incorporating tar with 5-20 per cent of the resin and emulsifying in hot water containing a small proportion of a soap.<sup>118</sup>

A preparation for rolling on tennis courts, footpaths or pavements is obtained<sup>119</sup> by coating sand with 5 to 6 per cent of a solution of cumarone or indene resin in a heavy petroleum distillate.

#### LINOLEUM AND OILCLOTH

In the manufacture of linoleum and oilcloth, cumarone resin is employed to some extent and the success attending its use depends largely upon the maker of the linoleum varnish composition.<sup>120a</sup>

Oilcloth is manufactured by impregnating a cotton cloth such as muslin, duck or canvas with several sizing coats made up of an emulsion of drying oil or clay, for example, in water. The coats are spread evenly on the fabric with a "doctor knife," the cloth being maintained under proper tension in order that the layers may be evenly distributed. After each sizing coat the cloth is dried before the next one is spread on. The last application may or may not contain cumarone resin, depending upon the finished article desired. The sizing solution must be of such consistency that it will adhere well to the cloth but at the same time it must not penetrate to the underside. In the case of colored oilcloths, the pattern is first printed on by engraved copper rollers, using a varnish containing a pigment. After the printing has dried a finishing coat of a long oil varnish is applied. In the case of white oilcloth the pigment is mixed with the finishing var-

<sup>119</sup> R. A. R. Jones and J. H. P. Burke, British P. 370,917, 1930; *Brit. Chem. Abs.* B, 1932, 602.

<sup>120a</sup> F. Frits (*Chem.-Ztg.*, 1933, 57, 997; *Chem. Abs.*, 1934, 28, 2925) has discussed the preparation of linoleum and the number of substances, including cumarone resin, which may be substituted for materials (linseed oil, rosin) originally used.

nish and the printing done after the film has dried. The pigments used vary according to the product desired and, particularly the white pigments, play an important part other than merely being the coloring agent. As an illustration, zinc oxide will produce oilcloth having a high gloss while lithopone yields a coating which is not quite as glossy though tougher and more durable. In using lithopone, however, a high gloss can be obtained by special methods. One procedure is to apply a light finish coat of good quality spirit varnish. In making white oilcloth, cumarone resin has caused some difficulty in the past by yellowing.

Lender and Koch<sup>120</sup> were apparently the first to utilize cumarone resin in the manufacture of linoleum and oilcloth. The resin was added to tung oil, which had been polymerized by heating to 220-240°C., and the resulting mass was mixed with ground cork and a pigment, and pressed on a cloth backing. Better results were reported by Priest when the cumarone resin was ground with the polymerized<sup>121</sup> or oxidized<sup>122</sup> vegetable oil at a temperature of 100°C. or below. The product, so obtained, was found by Priest<sup>123</sup> to be lighter in color and to have greater adhesive properties. The elastic, gummy mass was mixed with pigment, ground cork or wood meal, and applied to the fabric by pressure. A composition of similar properties obtained by mixing one part of cumarone resin with two parts of cold tung oil gel, or by mixing one part of resin with two parts of cold oxidized linseed oil, is incorporated with the other ingredients in the following proportions: Oil-cumarone resin composition, 50 parts; pigment, 20 parts; ground cork or wood meal, 50 parts.

A binding medium for cork and wood flour in the manufacture of linoleum was prepared by Baldwin<sup>124</sup> from a mixture of 50 parts of ester gum, 50 parts of cumarone resin, 35 parts of dibutyl tartrate, and 10 parts of polymerized linseed oil. To 40 parts of this molten binder, 10 to 40 parts of wood flour, cork dust, etc., and 40 to 45 parts of pigments or fillers are added.

Floor coverings consisting of felt saturated with a nitrocellulose solution containing cumarone resin have been described by Taylor.<sup>125</sup> For example, the coating solution may have the following composition: 12 parts by weight of nitro cotton, 88 parts by weight of a solvent mixture containing as high as 35 per cent of acetone oil diluted with 65 per cent of solvent naphtha. To this mixture there may be added 12 parts of linseed oil and 12 parts of cumarone resin.

#### FLOORING AND FLOOR TILE

One of the important developments in the use of cumarone resin has been its application in the manufacture of mastic flooring and floor tile.<sup>126</sup> These compositions were originally made with asphaltic binders, blended with a solvent, pigment and fillers. The demand for lighter colored flooring necessitated substitution of a binder with lower tinting power. Cumarone resin was found to be well suited for this purpose. Resistance to washing (due to its unsaponifiable nature) as well as its color proved to be decided advantages.

A hard, pale resin is ordinarily selected and plasticized with oils and pitches of such properties that a light-colored binder is secured. This is used to the extent of about 30 per cent with asbestos fiber, slate flour, powdered silica or

<sup>120</sup> R. Lender and A. Koch, U. S. P. 1,019,666, Mar. 5, 1912; *Chem. Abs.*, 1912, 6, 1377.

<sup>125</sup> C. M. Taylor, U. S. P. 1,562,383, Nov. 17, 1925; *Chem. Abs.*, 1926, 20, 272.

<sup>126</sup> J. A. Kenney, *Plastic Products*, 1934, 11 (2), 61.

whiting, as well as the proper pigments. The mixture is masticated on hot rolls or in heated Banbury mixers. The plastic mass, while still hot, is sheeted out on rolls, polished and cut into squares. Mottled, grained or marbled effects are obtained by mingling pieces of contrasting color before rolling out into flat plates.

Mastic flooring is prepared in a similar fashion, the presence of a solvent providing a more workable mass, which is applied by means of a trowel. The coating must then stand one or two days to dry and harden.

Satisfactory quality in both types of flooring depends on the skill and care of the manufacturer, particularly in regard to selection of materials. The amount of cumarone resin required may vary with the color desired. For medium light colors, bitumen may be incorporated with the cumarone resin binder, or a darker shade of the latter can be used. Asphalt alone, however, is only recommended for darker colors.

Polymerized tung oil was added to the cumarone resin binder by Bonney and Maguire<sup>127</sup> to produce a more resilient and lustrous mastic tile. For example, the following proportions were used:

Cumarone resin (3 parts) . . . . .	} 25 per cent
Tung oil (1 part) . . . . .	
Asbestos fiber . . . . .	
Pigments and mineral fillers . . . . .	
	30 per cent
	45 per cent

The oil was heated to 260-270°C. and 15 per cent of the resin added to cool it to about 230°C. The temperature was again raised to 260-270°C., after which heating was stopped and the oil allowed to polymerize. An oil-resin gel was formed and after some cooling was kneaded in a heated mixer with the fiber, fillers and the balance of the resin. The hot composition was rolled into sheets and cut to size.

#### FELT AND CLOTH SIZING

A composition for impregnating roofing felt which, at elevated temperatures, is more fluid than asphalt alone, consists of 60 to 98 per cent of asphalt of melting point not less than 32°C., together with 40 to 2 per cent of cumarone resin.<sup>128</sup>

Perry<sup>129</sup> prepared roofing felts by impregnating the watery pulp of beaten rags with an emulsion of cumarone resin and a saponified resin. The pulp was then dried in a continuous sheet by means of rolls but was not calendered as heavily as in the manufacture of paper. A similar emulsion for use in the waterproofing of fabrics was obtained by Roether<sup>130</sup> by adding paraffin, cumarone resin and linseed oil to an agitated and boiling solution of saponified coconut oil and tallow. Cloth was waterproofed by immersion in the warm liquid with subsequent wringing and calendering.

Eichler<sup>131</sup> produced a waterproof fabric or paper by impregnating the material with a cumarone resin varnish thinned to the desired consistency. It is stated that cloth woven from fibers which carry minute particles of cumarone resin may be advantageously used in lining shoes.<sup>132</sup> McCoy<sup>133</sup> used chlorinated cumarone com-

pounds for treating cloth, paper, and the like, to render the material suitable for use as electrical insulation. Shaffer<sup>134</sup> utilized a solution consisting of 1 part cumarone resin, 2 parts rubber, 2 parts paraffin and 20 parts of a hydrocarbon solvent for waterproofing leather and fabrics.

#### PAPER SIZE

Although cumarone resin has been employed in the preparation of sizing for paper,<sup>135</sup> it has not readily lent itself to this purpose because of its unsaponifiable nature. Ellis,<sup>136</sup> however, found that unsaponifiable resins could be utilized by blending them with a saponifiable resin (e.g., rosin) and then emulsifying with aqueous alkali. The emulsified mixture is added to the pulp from which the paper is to be prepared and calendered in the usual manner.<sup>137</sup> Muth<sup>138</sup> also melted rosin (or fatty material) with cumarone and afterwards boiled the mixture with sufficient alkali or ammonia to give a uniform emulsion. Alkali salts of sulphonated aromatic or naphthenic acids facilitated the latter operation.<sup>139</sup> The resulting emulsion is used for sizing paper or other fibrous material. Emulsifiable resins were produced by Ellms<sup>140</sup> through careful control of the washing treatment during the manufacture of cumarone resins so that the latter contain 0.3 to 1.9 per cent of total ash of which a large proportion should be sulphonate ash. The correct amounts of ash are also attained by blending the resin with paracumarone sludges or soaps from the first alkali wash. Strobel and Tallman<sup>141</sup> prepared emulsions for sizing paper by the use of a dispersing agent consisting of abietic acid or a fatty acid cooked with 10 per cent of its weight of sodium carbonate. One procedure consists in heating mixtures of cumarone resin, asphalt, copal or gilsomite with a drying oil and the emulsifying agent at about 260°C., and adding water while the mixture is still hot. Alum is used as the precipitant.

#### PRINTING INKS

Cumarone resin has been suggested as an ingredient to replace fossil gums in printing inks. Because of its neutral character it exerts no deleterious effect on color materials. It is reported that the resin, especially in admixture with lithographic varnishes, is used in making certain types of highly satisfactory printing inks.<sup>142</sup> Other advantages, such as improvement in the luster of the printed matter and an increase in the stability of color of the ink, are partly offset by price considerations.<sup>143</sup>

McElroy and Clarke<sup>144</sup> proposed to utilize as a printing ink vehicle a solution of cumarone resin in a neutral volatile solvent, such as terpeneol, with or without the addition of rosin oil to render the binder more plastic when dried. For example, 2¼ parts of bronze powder are incorporated with 1 part of a vehicle consisting

of 16 per cent cumarone resin dissolved in 79.8 per cent of terpineol and 4.2 per cent of rosin oil to make an ink of pasty or semi-fluid consistency. Other softening agents which may be incorporated with the resin to give a non-drying ink are dibutyl phthalate, butyl stearate, diamyl phthalate and triphenyl or tricresyl phosphate.<sup>145</sup>

A composition for transferring designs from a film on a paper base to silk, leather and paper is described by Poschel.<sup>146</sup> With alcohol as the transferring liquid, the following ingredients are used: dye, Carbitol, methyl alcohol, cumarone, blown castor oil, shellac, ethylene dichloride and Cellosolve. For lithographic printing an oil- or alcohol-soluble dye is mixed with a varnish comprising chlorinated biphenyl, cumarone resin, blown castor oil, elemi resin and elemi oil. Marston and Lawrence<sup>147</sup> obtained a transfer ink by adding boiled linseed oil, mineral oil, a drier and coloring matter to molten cumarone resin melting at 95-130°C. A marking composition includes ozokerite, blown vegetable oil and cumarone resin.<sup>148</sup>

An indelible medium for conveying designs from paper to textile fabrics consists of cumarone resin and an indelible printers' ink fused together to yield a homogeneous mass.<sup>149</sup> Another formula calls for 16 parts of cumarone resin, 4 parts of rosin, 4 parts of carnauba wax, 2 parts of doubly-pressed stearic acid, 8 parts of ultramarine blue, and 40 parts of a special white ink. The latter includes 78 per cent of Titanox (titanium dioxide and precipitated barium sulphate) and 22 per cent of litho varnish, ground to a paste.<sup>150</sup> A solid, fusible transfer material was prepared by Lawrence<sup>151</sup> from a paper base and a composition containing cumarone resin, ethyl- or benzylcellulose and various solvents, oxidized oils, and coloring materials.

#### MISCELLANEOUS USES

A number of miscellaneous applications of cumarone resin have been described indicating possible methods of utilization in electrical insulation, photography and tanning of leather. For example, the resin may be dissolved in oils, particularly those of the hydrocarbon class, to increase their viscosity for the impregnation of paper insulation of cables.<sup>152</sup> The addition of polymerized cumarone and indene is also said to improve lubricating oils as regards viscosity, pour point and stability.<sup>153</sup>

Cumarone resin has been proposed by Renner and Moeller<sup>154</sup> for use in the preparation of tanning liquors. By condensing and sulphonating the resin mixed with phenols, and then oxidizing the product to quinone-like compounds, a tanning agent was obtained.<sup>155</sup>

Cumarone resin mixed with hard rubber dust yields a moldable ebonite composition,<sup>156</sup> with phthalic anhydride, glycerol and linseed oil fatty acid furnishes

## Chapter 8

### Resins from Acetylene

The possibilities of acetylene as a raw material for the production of high grade resinous or resin-forming substances have only been realized during the last few years. Acetylene is a cheap and abundant raw material and, at the present time, its conversion to synthetic rubber-like substances, drying oils and similar products is being actively exploited by at least one large company in the United States. Although the principal source of acetylene at present is calcium carbide, considerable quantities are being manufactured by the action of an electric arc on both natural gas and the gases from petroleum cracking.<sup>1</sup>

The conversion of acetylene into high-molecular-weight, amorphous materials takes place by a process of additive polymerization. However, valuable synthetic products of this type are now being made by the action of various chemical reagents, including hydrogen chloride, hydrogen bromide and sulphur chloride, on the lower polymers of acetylene. Accordingly, it becomes necessary to consider the polymerization reactions of acetylene with particular reference to the production of high-molecular-weight, resinous and amorphous polymers and also of its lower highly unstable ones, which can themselves be converted into such amorphous substances.

#### POLYMERIZATION OF ACETYLENE

Acetylene may be polymerized by a large number of agents.<sup>2</sup> Among these may be mentioned heat, light, electricity and various chemical substances.

The thermal polymerization of acetylene at temperatures above about 400°C. has been studied by a large number of investigators.<sup>3</sup> At these elevated temperatures both in the absence and also in the presence of solid contact materials, condensation to liquid and tarry substances takes place readily. These polymers are mainly of an aromatic character and a large number of mononuclear and polynuclear aromatic hydrocarbons have been identified in the liquid products of the reaction. From the point of view of the formation of resinous bodies, the high temperature treatment of acetylene would appear to be of no practical importance.

As might be expected, the presence of certain catalysts causes acetylene to undergo condensation at comparatively low temperatures with the formation of products of a nature essentially different from those formed at higher tempera-

tures. Of the greatest importance is the extraordinary activity of metallic copper, which catalyzes the condensation of acetylene to a high-molecular-weight, amorphous substance at temperatures above about 180°C. The formation of this polymer, to which the name "Cuprene" has been assigned, is discussed fully at a later stage. Small amounts of cuprene-like materials are also produced from acetylene in the presence of metallic iron, nickel and cobalt at temperatures ranging from room temperature to about 400°C. but the main products of reaction in these cases consist of carbon, hydrogen and some oily substances.

Gambarjan<sup>4</sup> investigated the formation of a cuprene-like substance prepared by the reaction of bromine on a suspension of aluminum in chloroform. He found the essential reaction to be that of bromoform on aluminum probably yielding acetylene. This in turn reacted to form the solid in question.

The action of the silent electric discharge on acetylene gas, a subject investigated by a number of workers, gives rise to solid, insoluble and amorphous polymerization products as well as unstable liquids and gases. Among the gases are hydrogen and methane. Berthelot<sup>5</sup> observed that acetylene was converted, under the influence of the silent discharge into a thick, brown liquid, a brown solid and a small amount of gas. A semisolid, brown substance obtained by Jackson and Northall-Laurie<sup>6</sup> through subjecting acetylene to a high-frequency discharge was found by analysis to be a true polymer of acetylene, but it rapidly absorbed up to 8 per cent of oxygen when exposed to the air and was converted into an insoluble, hard solid. Losanitsch<sup>7</sup> reported that the silent electric discharge transformed acetylene into a thick, brown liquid, which later changed to a solid mass. The product could be separated by the use of an alcohol-ether mixture into a soluble, viscous substance and an insoluble solid. These materials rapidly absorbed oxygen on exposure to air.<sup>8</sup> Much light was thrown on the character of these polymers by Kaufmann<sup>9</sup> who obtained a viscous, brown liquid together with a brittle, pale yellow solid by passing a stream of acetylene through a silent discharge tube. The liquid product, which was formed exclusively when the reaction vessel was cooled, was rapidly polymerized to an insoluble solid on warming and on distillation left a plastic or brittle residue. The liquid rapidly absorbed oxygen and also formed an explosive silver derivative, implying the presence of acetylenic hydrocarbons. The solid formed in the discharge tube was a pale yellow, odorless powder insoluble in all solvents. Kaufmann considered this substance to be essentially aliphatic in nature as contrasted with cuprene which is thought by some investigators to be a polynuclear, aromatic material.

The lower, liquid polymers of acetylene have been obtained by Mignonac and de Saint-Aunay<sup>10</sup> through exposing the gas to a high-frequency discharge and cooling the electrodes to -60°C. The liquid, whose molecular weight determination indicated it to be composed of trimers of acetylene, was a mixture of several hydrocarbons and contained about 40 per cent of diacetylenes and no monoacetylenes. Its empirical formula has been calculated to be approximately  $(C_{10}H_8)_n$ .<sup>11</sup> Reduction of this mixture of trimers yielded hexane and, from the products of oxidation, the presence of dipropargyl,  $HC\equiv C-CH_2-CH_2-C\equiv CH$ , 3-methyl-1,4-pen-

tadiyne,  $\text{HC}\equiv\text{C}-\text{CH}(\text{CH}_3)-\text{C}\equiv\text{CH}$ , and 1,5-hexadiene-3-yne,  $\text{CH}=\text{CH}-\text{C}\equiv\text{C}-\text{CH}=\text{CH}_2$ , was inferred. The trimeric material slowly underwent polymerization to a brown resin.

When acetylene is exposed to light of wave length shorter than 2500-3000Å, it undergoes polymerization even at low temperatures with the formation of a yellowish-brown, amorphous solid, insoluble in most solvents. This material appears to be similar to cuprene.<sup>12</sup> Exposure of a saturated aqueous solution of acetylene to the light of a mercury arc yields a white, inert, insoluble polymer.<sup>13</sup> Benzene and anthracene derivatives have also been detected.<sup>14</sup> Mercury vapor exerts a catalytic effect on the polymerization of acetylene in ultraviolet light, according to Toul.<sup>15</sup>

Under the influence of alpha-radiation acetylene undergoes condensation with the formation of a voluminous, brownish-yellow, amorphous powder. Mund and Koch<sup>16</sup> found that this material did not melt at 300°C. but did not investigate its chemical nature. Lind and Bardwell<sup>17</sup> likewise obtained a yellowish powder, similar to cuprene, on exposure of acetylene to radium emanation. Lind, Jungers and Shifflett<sup>18</sup> observed that acetylene and heavy acetylene (from calcium carbide and heavy water) polymerized at equal velocities to solid cuprenes on exposure to γ-rays from radon.

The production of a yellow, amorphous, cuprene-like material from acetylene has also been observed to take place under the influence of cathode rays.<sup>19</sup> According to Marshall,<sup>20</sup> polymerization to a fluffy, yellow powder is the only reaction occurring under these circumstances, no elimination of hydrogen being noticed. When acetylene was heated during irradiation the yield of solid was not changed but the powder increased in density and assumed a darker color. On exposure to air, Marshall found that this polymer could absorb as much as 30 per cent of its weight of oxygen.

Moens and Juliard<sup>21</sup> noted that acetylene was rapidly converted into a yellowish-white powder when subjected to the action of a high-frequency electro-magnetic field.

#### THE POLYMERIZATION OF ACETYLENE TO CUPRENE

Cuprene,<sup>22</sup> or carbene, is a voluminous, yellowish-brown solid obtained by the condensation of acetylene in the presence of copper or alloys of copper at temperatures usually above 180°C. The production of this material by the action of acetylene at 230°C. on cuprous oxide, or more slowly in the presence of finely divided copper, was first reported by Erdmann and Köthner.<sup>23</sup> Passage of acetylene for 18 hours over one g. of cuprous oxide furnishes 7 g. of cuprene having an

apparent volume of no less than 300 cc. The material was at first considered by Erdmann and Köthner to be a complex, nonexplosive copper acetylide of the formula,  $C_6H_2Cu_3$ , but was shown later by Gooch and Baldwin<sup>24</sup> to consist of a mixture of copper or its oxide with a complex hydrocarbon. The experiments of these investigators showed further that, although metallic copper may induce polymerization of acetylene at comparatively high temperatures, the formation of cuprene is started at moderately low temperatures by an oxidizing action. The important role of oxygen in this process was subsequently confirmed by Kaufmann and his co-workers.

Sabatier and Senderens<sup>25</sup> found that reduced copper induced the polymerization of acetylene at 180-250°C. to a yellowish-brown mass. This material consisted of a substance of the empirical formula,  $(C_7H_8)_n$ , (to which the name "cuprene" was applied) mixed with about 1.5 per cent copper. In addition to cuprene, a greenish tar and also small amounts of saturated and unsaturated hydrocarbons were obtained. Sabatier and Senderens suggested that cuprene resulted from the interaction of an intermediate acetylide with fresh acetylene.

Valuable information regarding the mechanism of the formation of cuprene has been supplied by Kaufmann and Schneider.<sup>26</sup> Comparative experiments on the condensation of acetylene in the presence of reduced copper, cuprous oxide, cupric oxide and a residue obtained by heating anhydrous copper ferrocyanide in a current of air at 250°C. for 15 minutes showed that the last catalyst gave the best yields of cuprene. The physical character of the substance was altered by the catalyst employed and the duration of heating. Its empirical composition also varied between  $(C_{11}H_{10})_x$  and  $(C_{16}H_{10})_x$ . With short periods of heating, the product was loose and voluminous, but, on continued exposure to the reaction temperature, a cork-like body was obtained. The material made in the presence of the copper-ferrocyanide catalyst was yellow to light brown whereas the other catalysts furnished much darker products. Subsequent experiments of Kaufmann and Mohnhaupt<sup>27</sup> showed that the conversion of very pure acetylene to cuprene in the presence of fully reduced copper at 230-300°C. did not take place unless small amounts of oxygen were present. It was believed by these investigators that cuprene resulted from the formation of an additive compound of acetylene and cuprous or cupric oxide. Decomposition of this double compound was considered to furnish a highly active form of acetylene capable of undergoing profound reactions more rapidly than the ordinary inactive form, while the regenerated copper oxide could then activate more acetylene. Unlike the compounds obtained by the polymerization of acetylene under the influence of the silent discharge, alpha-radiation or actinic light, cuprene did not absorb oxygen in the cold. It was halogenated only with difficulty and was oxidized to mellitic acid by nitric acid. These facts led Kaufmann and Mohnhaupt to assign a polynuclear aromatic structure to cuprene.

According to Schläpfer and Stadler,<sup>28</sup> cuprene has been prepared by the Elektrizitätswerk Lonza A.-G. Passage of technical acetylene, diluted with an inert gas, over finely divided copper heated to 300°C. yielded 75-80 per cent of cuprene, 5.5-7 per cent of cuprene tar and 13-17 per cent of waste gases. A detailed examination of the tar by the above investigators showed that it consisted mainly of

aromatic hydrocarbons of the benzene and naphthalene series. Smaller quantities of olefins (hexenes and octenes) and small amounts of paraffin hydrocarbons boiling between 28-64°C. under 720 mm. were also present. The technical details of the manufacture of cuprene have so far remained a secret. It is known definitely, however, that the presence of oxygen (air) is a necessary factor and that copper or cupriferous bronze powders are used as catalysts at a temperature of 200-260°C. under slight pressure and with the combined action of dark electric discharges.<sup>30</sup> The addition of air, oxygen or an oxygen-supplying agent to the acetylene prior to condensation in order to increase the yield of cuprene has been described by Horwitz.<sup>30</sup> Lichtenhahn<sup>31</sup> prevented choking of the reaction tube by the use of a special stirring mechanism. Addition of 5-15 per cent of nitrogen to acetylene minimizes coking (which is very pronounced with pure acetylene owing to the highly exothermic nature of the reaction) and gives a more homogeneous and lighter-colored cuprene. In another process,<sup>32</sup> cuprene was produced by passing acetylene, diluted by an inert gas, through a suspension of copper-bronze in stearic acid, or paraffin oil containing copper oleate, heated to 300°C. Cuprene obtained in this manner is finely powdered and light to dark brown in color. Addition of air or oxygen to the contact medium has been found advantageous.

In the process of de Liefde,<sup>33</sup> cuprene having strongly absorbent properties and useful as a decolorizing material is prepared by subjecting acetylene at 200-400°C. to the action of a metal or metal oxide catalyst (copper, nickel or iron or their oxides) containing a small amount, usually less than 1 per cent, of magnesium. Cuprous oxide with one per cent of stannic oxide converted acetylene to a soft, flocculent product at 180-245°C. and to a brittle, porous substance at 250-260°C., according to Davis and Levy.<sup>34</sup> Sabatier and Mailhe conducted benzyl alcohol vapors over titanium, tungsten and aluminum oxides and obtained a resinous hydrocarbon having the elementary formula,  $C_7H_6$ . The resin is insoluble and appears to be somewhat analogous to cuprene.<sup>35</sup>

#### INDUSTRIAL USES OF CUPRENE

Because of its chemical inertness and highly voluminous structure, cuprene offers possibilities for a large number of industrial applications. Herzog<sup>36</sup> has discussed its use in the manufacture of acid-resistant and electric-insulating materials, plastic masses, electrodes and explosives, as a cork substitute in linoleum manufacture and as an absorbing agent for illuminating materials, fuels and volatile substances. It can be used as a substitute for carbon in black powder and other explosives, an absorbent in liquid-air explosives, a component of detonators and a substitute for kieselguhr.

Finely ground cuprene has been used by Sulser<sup>37</sup> in conjunction with a linoleum cement for the production of linoleum. It replaced the usual cork dust or wood

flour. Cuprene possesses the advantage for this purpose that it is resistant to moisture and therefore not liable to rot.

Lepsius<sup>38</sup> proposed cuprene saturated with a liquid combustible material as a fuel. Cuprene is stated to be capable of absorbing large quantities of liquid and to have a high calorific value. An elastic composition of durable character has been prepared by Kühn<sup>39</sup> by mixing cuprene with a rubber composition. Plastic masses which could be used in electrical or heat insulation have been manufactured by heating an excess of the condensation products of acetylene with sulphur and an inert material (e.g., asbestos) together with the residues from the distillation of natural resins or oils boiling above 350°C. from tar distillation.<sup>40</sup> Grimwood<sup>41</sup> suggested the substitution of cuprene for all or part of the charcoal used in time rings for shell fuses. Absorbent masses for various purposes are obtained by activating cuprene through heating it for one hour or more in hydrogen at 400-700°C.<sup>42</sup>

Sulphurized cuprene, containing 11 per cent of sulphur, can be prepared by heating cuprene with sulphur monochloride in a reflux apparatus employing benzene as suspending agent. By operating under 10 atmospheres pressure at 180-200°C., a product containing 13.6 per cent of sulphur and 4 per cent of chlorine was obtained. These materials may find application in the rubber industry.<sup>43</sup>

#### CONTROLLED POLYMERIZATION OF ACETYLENE TO LOW-BOILING, UNSATURATED POLYMERS

One development in the conversion of acetylene into resinous and rubber-like materials has resulted from a study of the controlled polymerization of that hydrocarbon at ordinary temperatures under the influence of a solution of ammonium and cuprous chlorides. Under these conditions acetylene is polymerized to a dimer and a trimer, both of which may be utilized as raw materials for the manufacture of synthetic drying oils, resins and rubber-like substances. The fundamental discovery of the conversion of acetylene into its highly unsaturated, lower polymers by controlled polymerization is due to Nieuwland and his associates. Preliminary observations of the conversion of acetylene into some other material by catalytic action of a solution of cuprous chloride and sodium or potassium chloride were made by Nieuwland as early as 1906, but it was not until 1921 that the idea of using concentrated, cuprous chloride solution occurred to him. Such concentrated, cuprous chloride solutions were attainable by the use of ammonium chloride or amine salts. Divinylacetylene, or 1,5-hexadiene-3-yne, was the first polymer to be definitely identified among the products of reaction.<sup>44</sup>

When acetylene is passed into a concentrated solution of cuprous ammonium chloride, rapid absorption takes place with the formation of a complex compound. If this complex is heated soon after its formation, acetylene is evolved practically quantitatively. After the solution is allowed to stand at room temperature for a period of 120 hours or longer, no acetylene appears in reaction products; but, instead, polymers of acetylene with molecular weights corresponding to the formulas  $C_4H_4$  and  $C_6H_6$ . The mechanism of the reaction, as envisaged by Nieuw-

land, Calcott, Downing and Carter,<sup>46</sup> consists in the formation of a complex cuprous salt which is in equilibrium with normal acetylene and an activated form of acetylene, possibly  $\text{C}=\text{CH}_2$ . A slow combination of this activated acetylene molecule with one of normal acetylene follows, producing monovinylacetylene, butenyne, according to the scheme:

Two molecules of monovinylacetylene, in the presence of the cuprous ammonium chloride solution, unite to give a tetramer of acetylene (which is probably 1,5,7-octatriene-3-yne). The latter substance is formed by the addition of an activated vinylacetylene to a normal molecule of that compound, thus:

In the presence of acetylene, monovinylacetylene and activated acetylene may react to form divinylacetylene according to the equation,

From the commercial standpoint the most valuable of these polymers of acetylene are monovinylacetylene and divinylacetylene. The latter can be obtained in good yields by a fairly simple procedure. Since monovinylacetylene so readily reacts with more acetylene, the preparation of good yields of it is more difficult.<sup>46</sup> A satisfactory laboratory method for the synthesis of divinylacetylene is as follows:<sup>47</sup>

A mixture of 1000 g. of cuprous chloride, 390 g. of ammonium chloride, 100 g. of precipitated copper powder, 30 g. of hydrochloric acid (37 per cent) and 425 g. of water is introduced into a 2 liter flask and heated on a steam bath (in the absence of air) until all the copper is in the cuprous state. The catalyst is cooled to room temperature and charged by sweeping the air from the flask with a stream of acetylene and then continuing a slight pressure of that gas while agitating the catalyst. During absorption, the latter may warm up and a temperature of 40-50°C. can be attained without damage. Over 100 g. of acetylene will be absorbed and the catalyst becomes light yellow in color as insoluble addition compounds are formed. The mixture is allowed to age at room temperature for 5-7 days and then distilled by heating in an oil bath at 100-110°C. (still temperature), until only water comes over. The lower aqueous layer of the distillate is separated and returned to the catalyst mixture for re-use.<sup>48</sup> The oily layer is dried and distilled *in vacuo* on a water-bath. Divinylacetylene comes over under about 200 mm. pressure and the tetramer under about 20 mm. The yields, based on the acetylene absorbed, are: divinylacetylene, 70-80 per cent; tetramer, 10 per cent; and loss, 10-20 per cent. Divinylacetylene, which forms explosive substances on exposure to air, is best stored in the catalytic mixture and distilled immediately prior to use.

Nieuwland<sup>49</sup> has described the production of various derivatives of acetylene containing the group,  $\text{CH}_2=\text{CH}-$ , or its tautomeric form,  $\text{CH}_2-\text{CH}=\text{X}$ , where X is an atom of carbon, nitrogen, oxygen or sulphur bound by a double bond to the ethylidene group. The preparation of two of these, divinylacetylene and the acetylene tetramer, has been described above. Ethylidene aniline and its polymers

<sup>46</sup> J. A. Nieuwland, W. S. Calcott, F. B. Downing and A. S. Carter, *J.A.C.S.*, 1931, 53, 4197.

<sup>47</sup> For laboratory preparation of monovinylacetylene, the method of R. Willstätter and T. Wirth (*Ber.*, 1913, 46, 538; *Chem. Abs.*, 1913, 7, 1508) is recommended. This procedure involves the distillation of the quaternary base,

See also E. A. Shilov, A. N. Makashina and G. I. Yakimov (*Sintet. Kautchuk*, 1933 (1), 4; *Chem. Abs.*, 1933, 27, 5052) for modifications of the procedure.

<sup>48</sup> J. A. Nieuwland, W. S. Calcott, F. B. Downing and A. S. Carter, *loc. cit.*

<sup>49</sup> The catalyst can be used repeatedly over long periods without diminution of polymerizing power.

<sup>49</sup> J. A. Nieuwland, U. S. P. 1,811,950, June 30, 1931, to E. I. du Pont de Nemours & Co., *Chem. Abs.*, 1931, 25, 4892. *British P.* 384,654, 1932; *Chem. Abs.*, 1933, 27, 4251. *French P.* 733,663, 1931; *Chem. Abs.*, 1933, 27, 1011. *German P.* 538,283, 1933; *Chem. Abs.*, 1934, 28, 1360.

were obtained by introducing acetylene into a mixture of 2 parts of cuprous chloride powder and 100 parts of amline at 70-110°C. Vinyl chloride may be synthesized by using a mixture of ammonium and cuprous chlorides in hydrochloric acid (sp. gr. 1.194) at 20-40°.

The process has been made continuous by Calcott and Downing.<sup>60</sup> They pass the stream of acetylene rapidly in contact with the heated catalyst mixture in order to favor the formation of the dimer, vinylacetylene, over that of the trimer, divinylacetylene. Nieuwland<sup>61</sup> has improved the catalyst used by bringing the  $p_H$  to 6 or lower through incorporation of an inorganic or carboxylic acid which does not precipitate cuprous copper. In addition to these variations, the vinylacetylene may be continuously removed by a counter-current stream of mineral oil<sup>62</sup> or the reaction carried out in a non-aqueous solvent such as ethylene glycol.<sup>63</sup>

An essentially neutral solution of ammonium chlorocuprite is employed by Perkins and Toussaint<sup>64</sup> to secure a maximum yield of monovinylacetylene. The catalyst is prepared by dissolving 300 g. cuprous chloride, 300 g. ammonium chloride and 70 cc. concentrated hydrochloric acid in 600 cc. of water, heating to 90°C. and filtering. After saturating with acetylene, ammonium hydroxide is added until a black precipitate forms. This is dissolved with the minimum amount of hydrochloric acid. When acetylene is passed through at about 70°, a yield of 24 per cent vinylacetylene and 3 per cent higher boiling compounds is obtained.

#### MONOVINYLACETYLENE, $\text{CH}_2=\text{CH}-\text{C}\equiv\text{CH}$

This material is a colorless liquid boiling at +5°C. at 757 mm. and having the sharp but sweet odor associated with synthetic butadiene. Its density is given by the equation  $d_4^{20} = 0.7095 - 0.00114t$  for temperatures between -3° and -80°C. It congeals to a crystalline mass at the temperature of liquid air. Its structure is proved by the fact that it can be hydrogenated to n-butane and hydrated in the presence of mercuric sulphate and sulphuric acid to yield the unsaturated ketone 1-butene-3-one (methyl vinyl ketone),  $\text{CH}_2=\text{CH}-\text{CO}-\text{CH}_3$ .<sup>65</sup> The presence of acetylenic hydrogen is indicated by its ready formation of a white silver derivative and a yellow copper salt. Alcohols<sup>66</sup> combine readily with vinylacetylene to yield ethers. For example, 4-methoxy-2-butyne ( $\text{CH}_3\text{C}\equiv\text{CCH}_2\text{OCH}_3$ ) results when methyl alcohol containing a little sodium methylate is treated with vinylacetylene. In this instance addition of alcohol to the unsaturated hydrocarbon probably takes place at the 1,4 positions followed by rearrangement of the intermediate product.

Although the formation of a solid from monovinylacetylene by the action of  $\alpha$ -particles has been reported by Heisig,<sup>67</sup> from the industrial viewpoint the most important property of monovinylacetylene is its conversion into monohalobutadiene by combination with hydrogen chloride or hydrogen bromide, a reaction

discussed later. Under pressure, vinylacetylene is readily polymerized by heat to form viscous drying oils<sup>58</sup> and finally hard, resinous polymers. All the nonresinous substances formed in this way contain acetylenic hydrogen and probably possess formulas of the types:<sup>59</sup>

In the presence of acids, a considerable amount of styrene is formed also. This may be considered as a dimer of monovinylacetylene.

Polymerization may be controlled so as to yield an oily polymer which is completely nonvolatile at 100°C. under ordinary pressure. The danger of forming explosive compounds may be avoided by carrying out the reaction in a nonoxidizing atmosphere as was reported by Calcott and Downing.<sup>60</sup> The synthetic drying oil will absorb oxygen and halogens, the rate of reaction being greater, the lower the degree of polymerization. On the other hand the polymerization may be carried to the hard, brittle, resinous stage. Such a hard resin is obtained by heating vinylacetylene with 1 per cent of benzoyl peroxide for 200 hours at 110°C. It is insoluble in all solvents and does not react with the oxygen of the air or with halogens. Moreover, it is practically unchanged by treatment with strong sulphuric acid, strong alkalis or other corrosive agents, but is slowly oxidized by strong nitric acid.<sup>61</sup> The nonvolatile, liquid polymers constitute a class of drying oils suitable for compounding as paints and lacquers. The properties and use of these polymers are described later along with those of similar products from divinylacetylene.

### VINYLA CETYLENE DERIVATIVES

The preparation of vinylacetylides<sup>62</sup> from vinylacetylene and alkali metal amides (e.g., sodamide) has made possible the synthesis of a wide variety of vinyl ethynyl derivatives. Included among these are the carbinols (obtained by reaction between the acetylide and ketones or aldehydes) which polymerize readily to transparent resins.<sup>63</sup> The following reactions take place when sodamide and acetone are employed:

<sup>58</sup> A. S. Carter and F. B. Downing, U. S. P. 1,896,162, Feb. 7, 1933, to E. I. du Pont de Nemours & Co.; *Chem. Abs.*, 1933, 27, 2591. See also O. Jordan, H. Hopff and E. One method for making the vinylacetylide is to add powdered sodamide to a solution of monovinylacetylene in liquid ammonia, benzene or an ether. The mixture is stirred several hours and the solvent then evaporated, leaving a white powder (sodium vinylacetylide). Substitution of lithium or potassium amide for sodamide gives analogous products. All of these alkali vinylacetylides are highly reactive toward air, water and carbon dioxide. Hence it was found advisable, in forming vinyl ethinyl compounds, to add the acetone (or other reagent) directly to the acetylide before the latter had been isolated from the solvent, or even to carry out the two reactions simultaneously. For example, 15 mols of acetone and 18.8 mols of vinyl acetylene were thoroughly mixed (keeping the reaction vessel cold) and 16.5 mols of powdered sodamide added over a period of two hours. Following 4 hours more stirring, a large quantity of water was added carefully. The oily layer which formed was separated, washed with dilute sulphuric acid and distilled. A yield of 898 g. of vinyl ethinyl dimethyl carbinol (b.p. 67°C. at 24 mm.) was secured. Methyl ethyl ketone, methyl octyl ketone, acetaldehyde and butyraldehyde formed homologous products. Crotonaldehyde, benzophenone and acrolein reacted to give resinous solids, due probably to polymerization during the condensation.

Vinylethinylcarbinols were found to polymerize readily in light and air, reaction being accelerated by metallic halides, oxidation accelerators (benzoyl peroxide, sodium perborate) and by catalysts of photochemical polymerization, e.g., uranyl nitrate. The ultimate product is a hard, insoluble, glass-like resin, but the intermediate stages range from thin syrupy substances to rubbery solids, all soluble in organic solvents but capable of further hardening. It is stated that polymerized carbinols, as well as the intermediate products, are compatible with nitrocellulose, drying oils and resins thus indicating their possible use in the preparation of lacquers, enamels, impregnants, varnishes and molded articles. For example, a light polymer was made by exposing a solution of equal parts of methyl ethyl vinyl ethinyl carbinol and toluene, containing 0.5 per cent benzoyl peroxide, to a Cooper-Hewitt light for 62 hours. The colorless solution (50 parts) was then mixed with lacquer thinner (100 parts) and pyroxylin base (57.8 parts). A dry film resulted after one hour at room temperature.

The ester derivatives of vinylacetylene present another source of resinous bodies. Organic carboxylic esters of 1,3-butadienol were prepared by Werntz<sup>64</sup> by passing monovinylacetylene into the organic acid. A mercury salt (mercuric sulphate) served as a catalyst, usually assisted by sulpho-acetic acid and acetic anhydride. The reaction proceeds according to the scheme:

For example, 10 g. of mercuric oxide were dissolved in 200 g. of hot glacial acetic acid and 10 g. of acetic anhydride added after cooling. Four grams of fuming sulphuric acid were then run in slowly, with stirring, to precipitate finely divided mercuric sulphate. Into this agitated mixture was fed a slow stream of monovinylacetylene, 1.5 hours being required for the addition of 173 g. The initial temperature was 12°C. but this was lowered to 0-5°C. by use of an ice bath and was so maintained during the reaction. All of the monovinylacetylene was absorbed. The resultant liquid was poured into a saturated salt solution, causing separation of a brown oil. On washing and vacuum distilling, 13 g. of liquid (b.p. 32-70°C. at 12 mm.) were secured.

Similar reactions were carried out using butyric, formic and chloroacetic acids.

<sup>64</sup> J. H. Werntz, U. S. P. 1,963,108, June 19, 1934, to E. I. du Pont de Nemours & Co.; *Chem. Abs.*, 1934, 28, 4745. See also J. H. Werntz, *J.A.C.S.*, 1935, 57, 204.

At 25°C. the yields were somewhat higher than at 0-5°C. but appreciable amounts of resin were also formed.

Esters of butadienol polymerize spontaneously, but the action is accelerated by pressure, heat, light and catalysts (acids, alkalies, peroxides, stannic chloride). The products, depending on the degree of polymerization, may be soluble resinous bodies, less soluble rubbery substances or insoluble materials resembling vulcanized rubber. Their properties vary somewhat depending on the organic acid used and may be further modified by the admixture of fillers, drying oils, natural or synthetic resins, plasticizers and cellulose nitrate or acetate. The resinous polymer form, made by heating the ester in an organic solvent, dries and further polymerizes to a clear, dry, flexible film, indicating the possibility of use in varnishes, lacquers and impregnants. Molding compositions containing the partially polymerized resins were also suggested. An emulsion of the original ester may be heated to create a latex reported to be comparable with natural rubber.

#### DIVINYLACETYLENE

This is a colorless liquid, which possesses an unusual allhaceous odor and rapidly assumes a straw color on exposure to light. It boils at 83.5°C. under 760 mm. and at 50° under 240 mm.,  $D_4^{20} = 0.7851$ .<sup>65</sup> Its chemical constitution can be inferred from the fact that it is reduced to n-hexane, does not contain an acetylenic hydrogen and yields on bromination two stereo-isomeric hexabromo-3-hexenes, melting at 81° and at 114°. The presence of two vinyl groupings is shown by its ready combination with two molecules of thio-p-cresol to furnish 1,6-di-(p-tolylthio)-3-hexyne, melting at 74.5-75.5°. On chlorination it is converted into a complex mixture of chlorides up to a hexachloride.<sup>67</sup> Treatment with aqueous hydrochloric acid gives first a monohydrochloride and then, very rapidly, a dihydrochloride, the latter substance having the constitution,<sup>68</sup>  $\text{CH}_3\text{—CH=CH—CCl=CH—CH}_2\text{Cl}$ . Although pure divinylacetylene undergoes thermal decomposition at 105-110°, yet it may be polymerized smoothly at lower temperatures in an inert atmosphere to viscous and, finally, hard, brittle, resinous polymers.

The most important application of divinylacetylene is in the production of synthetic drying oils which give coatings very resistant to corrosion by most chemical reagents. When divinylacetylene is exposed to air it rapidly absorbs oxygen to form highly explosive, peroxide-like compounds which have been found to detonate with violence on standing. Under the influence of heat, or by aging at ordinary temperatures, in the presence of air, divinylacetylene is transformed successively into an oily product, largely soluble in alcohol and acetone, to a gelatinous material, soluble in acetone and partly insoluble in alcohol, then to a resinous mass, insoluble in alcohol and slightly soluble in acetone, and finally to a hard, brittle polymer completely insoluble in acetone and alcohol. In preparing these products the formation of explosive substances is prevented by maintaining the temperature well below 113°C., best at 85-87°C.<sup>69</sup>

A synthetic drying oil has been made by Collins<sup>70</sup> through polymerization of

<sup>70</sup> A. M. Collins, U. S. P. 1,812,544, June 30, 1931, to E. I. du Pont de Nemours & Co.; *Chem. Abs.*, 1931, 25, 5049.

divinylacetylene by heat. Thus a 12-18 per cent yield of viscous, non-volatile oil is produced by boiling divinylacetylene for 4 hours in the presence of air under a reflux apparatus (temperature of the boiling liquid, 85-90°C.) and distilling off unchanged divinylacetylene under reduced pressure. Alternatively, a mixture of 75 per cent of divinylacetylene and 25 per cent of a tetramer of acetylene is boiled with refluxing at 75-80° at atmospheric pressure for 5 hours in an atmosphere of nitrogen. An equal weight of xylene is added and the mixture distilled, leaving as a residue a clear reddish-orange liquid of relatively low viscosity, having good drying properties and requiring no thinning before use. The yield in this case is about 50 per cent based on the acetylene mixture used. Some acetylene tetramer in the raw material is said to be advantageous in increasing the yield of drying oil. A lacquer which can be brushed on metals is obtained by mixing 500 g. of a 50 per cent solution of polymers (obtained from divinylacetylene and tetramer) in xylene with 100 g. of a 50 per cent solution of metastyrene in the same solvent.

Polymerization of both vinylacetylene and divinylacetylene while in the form of a flowing stream has been described by Calcott and Downing.<sup>71</sup> In the production of drying oils from divinylacetylene and acetylene tetramer by polymerization, better results are secured by effecting reaction in the presence of an added solvent at the boiling point.<sup>72</sup> A 25 per cent yield of drying oil is obtained by refluxing a mixture of equal weights of pure divinylacetylene and xylene for 24 hours at 85-90°C. in the presence of air. By heating the tetramer of acetylene in a closed vessel at 100° for 3 hours, an almost quantitative yield of a practically non-volatile oil is secured. This oil is used as a lacquer or varnish. A practically complete conversion into film-forming polymers is also obtained by boiling 40 g. of dibutylamine, 1000 g. of crude divinylacetylene, containing 40 per cent of tetramer, and 1000 g. of xylene under reflux in an atmosphere of nitrogen for 50 hours. The product in this case is a clear, reddish orange liquid of relatively low viscosity, having good drying properties and requiring no thinning before use. Collins found that non-volatile liquid materials in any stage of polymerization between that represented by an average molecular weight of 156 and that just short of the formation of a gel can be used as synthetic drying oils.

The synthetic drying oils produced by partial polymerization of divinylacetylene and the tetramer of acetylene have been marketed under the name "S-D-O."<sup>73</sup> This coating composition consisted of a solution of the partially polymerized acetylene polymer in an aromatic hydrocarbon solvent. The pure polymers themselves continued to polymerize at normal temperatures, even in the absence of air. However, when diluted with a solvent, spontaneous polymerization did not occur and the material could be stored at normal temperatures in the absence of air and light. When applied to a surface, the solvent rapidly evaporated leaving a film of "S-D-O" base which dried out quickly to a hard, transparent, amber-colored resin. Drying out was much more rapid than with the usual drying oils because polymerization was accelerated by a very small amount of absorbed oxygen. The dried films were more impervious to moisture than equally thick films of linseed oil paint<sup>74</sup> and were not attacked by chlorine, bromine, brine, ammonia (either anhydrous or in solution), hydrogen sulphide, crude oil or refined petroleum. The only chemicals that did attack these polymerized films were strong oxidizing

<sup>71</sup> W. S. Calcott and F. B. Downing, U. S. P. 1,950,429, Mar. 13, 1934, to E. I. du Pont de Nemours & Co.; *Chem. Abs.*, 1934, 28, 3271.

<sup>72</sup> A. M. Collins, U. S. P. 1,812,849, June 30, 1931, to E. I. du Pont de Nemours & Co.; *Chem. Abs.*, 1931, 25, 5048.

<sup>73</sup> O. M. Hayden, *Ind. Eng. Chem.*, 1932, 24, 563; see also *Chem. Met. Eng.*, 1932, 39, 517.

<sup>74</sup> H. Scheiber (*Farbe u. Lack*, 1934, 326, 339; *Brit. Chem. Abs.* B, 1934, 803) finds, however, that drying oils prepared from polyvinyl compounds are inferior to natural oils from the standpoint of adhesion, as well as in the toughness and hardness of the dry film.

agents, such as concentrated hydrogen peroxide, chromic acid, nitric acid and hot, concentrated, sulphuric acid. Hydrofluoric acid penetrated these films but did not destroy them. The fully polymerized films were not thermoplastic and withstood temperatures as high as 200°C. without change. These synthetic drying oils can be applied as paints to almost any surface other than glass or enamel. Laboratory tests indicated the possibility of using this type of protective covering for silo walls.<sup>76</sup> In using "S-D-O" paints, successive coatings must be applied before the previous coat has fully hardened or else preceding coats must be treated similar to a metal surface, i.e., roughened by a sand-blast or other means.

Toxic coatings for ship bottoms were suggested by Calcott and Downing<sup>76</sup> as an application for synthetic drying oils from acetylene polymers. Toxicity is supplied by incorporation of isopropyl-naphthalene or dinitrochlorobenzene in the composition. Divinylacetylene may be converted into a rubber-like material by a process due to Calcott, Downing and Powers.<sup>77</sup> The divinylacetylene is first emulsified with water to give an emulsion of grain size similar to that of natural Hevea rubber latex, or approximately a diameter of 1 micron. This emulsion is then polymerized either by allowing it to stand at 30°C. for a week, by heating or by the addition of sufficient 2 per cent acetic acid to change the  $pH$  to about 4. The coagulum is freed from water by milling and is ready for use as a rubber substitute. Physically the products obtained from divinylacetylene in this manner are said to resemble raw rubber and are characterized by a high degree of elasticity.

According to Calcott, Carter and Downing,<sup>78</sup> divinylacetylene may be partially hydrogenated (using a nickel catalyst) and the resulting material polymerized (with benzoyl peroxide) to secure resins soluble in organic solvents and stable to light. Compounds of this type, either alone or mixed with natural gums and resins, can be incorporated with pigments, drying oils, volatile solvents and fillers to form paints and varnishes.

#### HALOGENATED DERIVATIVES OF ACETYLENE POLYMERS AND THEIR APPLICATION

Considerable technical and scientific interest is centered round the products obtained by treating monovinylacetylene with halogen acids since it has been found that the resulting halogenobutadienes are capable by controlled polymerization of being converted into rubber-like materials of great industrial promise. On shaking monovinylacetylene with aqueous concentrated hydrochloric acid, two compounds are produced, namely 4-chloro-1,2-butadiene and 2-chloro-1,3-butadiene, or "chloroprene," as the latter substance has been named. The former compound is probably the initial product of the reaction, but it speedily undergoes isomerization to chloroprene especially in the presence of certain catalysts. The most active catalyst mentioned is a solution of cuprous chloride in hydrochloric acid.<sup>79</sup> Accordingly, the reaction between vinylacetylene and hydrochloric acid in the presence of cuprous chloride at 0-20°C. gives almost quantitative yields of chloroprene in a few hours. On prolonged contact of vinylacetylene with hydrochloric acid especially with cuprous chloride as a catalyst, two molecules of hydrochloric acid are

<sup>80</sup> W. H. Carothers, G. J. Berchet and A. M. Collins, *J.A.C.S.*, 1932, 54, 4066. See also W. H. Carothers and G. J. Berchet, *J.A.C.S.*, 1933, 57, 2807.

added with the formation of 2,4-dichloro-2-butene. The complete reaction scheme may be formulated as follows:

The original method of Carothers and Collins<sup>80</sup> which involved shaking the catalyst and reactants in batches was later transformed by Downing, Carter and Hutton<sup>81</sup> into a continuous process. The latter is similar to that for the preparation of vinylacetylene<sup>82</sup> in that the reactants are passed continuously over the catalyst solution heated between 30-60°C. The products are removed by the stream of unreacted vinylacetylene and condensed. The vinylacetylene is then returned to the reaction vessel. Either chloroprene or 2,4-dichloro-2-butene may be formed. Rapid passage of the gases favors the formation of chloroprene, over 90 per cent yield being obtained. Collins<sup>80</sup> has combined the transformation of acetylene to vinylacetylene and the latter to chloroprene into one step. The distillate from the reaction mixture contains 24.3 per cent of chloroprene, 30.2 per cent of divinylacetylene and 30.0 per cent monovinylacetylene which are separated by fractional distillation. The laboratory preparation of chloroprene has been described by Carothers, Berchet and Collins<sup>84</sup> and by Zelinski, Kozlov and Shter.<sup>85</sup>

Of the two monohydrochlorides of vinylacetylene, only chloroprene is of industrial importance. The accompanying isomer, 4-chloro-1,2-butadiene is a colorless liquid boiling at 87.7-88.1°C. and shows no tendency to polymerize.<sup>86</sup> It can be stored unchanged for many months under laboratory conditions and even undergoes no change when submitted to a pressure of 6000 atmospheres for 45 hours at 50°.<sup>87</sup> On the other hand, chloroprene possesses an unusually pronounced tendency to polymerize to rubber-like substances, some of which would appear to have industrial possibilities.

Chloroprene,  $\text{CH}_2=\text{CCl}-\text{CH}=\text{CH}_2$ , is a colorless liquid of  $d_4^{20}$  0.9583 and boiling at 59.4°C. under 760 mm. The presence of a conjugated system of double bonds in the molecule of this compound is demonstrated by its ready combination with maleic anhydride and naphthoquinone to furnish crystalline addition products.<sup>88</sup>

As previously mentioned, chloroprene is distinguished by its rapid change to rubber-like and resinous products,<sup>89</sup> transformation being complete in a few days. In comparison, the spontaneous polymerization of isoprene requires several years for completion. In the case of chloroprene, conversion is greatly accelerated by

keeping the concentration of the polymer below 15-18 per cent through the addition of solvent from time to time. Carothers, Collins and Kirby<sup>90</sup> polymerized 2-chloro-1,3-butadiene in a number of different solvents. These included volatile liquids (benzene, toluene, ether, ethylene chloride and carbon disulphide), non-volatile oils (mineral oil, cottonseed oil, ethyl benzoate, corn oil and cod-liver oil) which remain in the polymer and modify its properties, and solvents which precipitate the resin as it is formed (ethyl alcohol). In this manner not only can polymerization be controlled, but a wide variation is also possible in the nature and application of the resulting substances. In addition, co-polymers of the chlorobutadiene with styrene, isoprene or tung oil have been formed. The latter products were said to be plastic and usually transparent.

Several other types of amorphous polymers of chloroprene have been recognized by Carothers and his co-workers but the most important from an industrial standpoint are the  $\alpha$ - and  $\mu$ -polymers.

$\alpha$ -Polychloroprene is best obtained by exposing chloroprene to strong illumination from a Mazda lamp or a mercury arc at 35°C. for twenty-four hours. Under these conditions about 30 per cent of the chloroprene is polymerized and the  $\alpha$ -polymer can be isolated by pouring into alcohol. This polymer is plastic and dissolves completely in benzene to form highly viscous solutions. It can be calendered into thin sheets or extruded with the usual rubber material. At 30°C. the  $\alpha$ -polymer is completely changed in 48 hours (or in 5 minutes at 130°C.) into the  $\mu$ -polymer. This change, which corresponds to the vulcanization of rubber, does not require the addition of sulphur but can be effected by heat alone and is accelerated by zinc chloride or butyrate, ferric chloride, or primary aromatic amines. Transformation of chloroprene occurs very readily also in aqueous emulsion and the product constitutes a synthetic (vulcanized) latex<sup>91</sup> which has about the same particle size as good Hevea latex and may be used in much the same way.

One method for preparing the latex is to agitate 2-chloro-1,3-butadiene with an equal weight of water in which has been dissolved 2 per cent by weight of sodium oleate.<sup>92</sup> Heat is evolved as the emulsion forms and the mixture must be cooled. A milk-white suspension results in which the particles show a definite Brownian movement. Polymerization is complete after a few hours, but may be retarded by small amounts of iodine or catechol. In this case the dispersed bodies are plastic, soluble in benzene and resemble natural unvulcanized rubber. As in the natural latex, precipitation or coagulation may be accomplished by addition of acid. Ordinary rubber antioxidants (aromatic amines and phenols) as well as acid acceptors (alkalies, zinc oxide, sodium oleate) are said to inhibit oxidation of the synthetic material. The use of protective colloids, i.e., casein, albumen, natural latex serum, pectins and gum arabic, in the latex is also recommended.

Barrett and Dorough<sup>93</sup> replaced sodium oleate with the sodium or ammonium salt of glyceryl phthalate resin. In some instances the polybasic acid was blended with 20-35 per cent of castor oil, stearin, tung oil or cottonseed oil previous to esterification. Chloroprene latices prepared in this manner are said to give films with improved tensile strength, tear resistance and elasticity.

By incorporating 2 per cent of an oxidizing agent, e.g., potassium persulphate

or sodium perborate, with a sodium oleate dispersion of chloroprene, Collins<sup>100</sup> is reported to have secured coagulated films and threads which on drying showed improved tensile strength, especially after aging at 80°C.

$\alpha$ -Polychloroprene has been placed on the market in the form of a synthetic rubber named DuPrene.<sup>101</sup> This product has excited a vast amount of interest,<sup>102</sup> and numerous studies have been made comparing it to natural rubber<sup>103</sup> and investigating the compounding of DuPrene with other substances to improve its

g. 46.

Flex-Cracking Test of DuPrene. Natural rubber shown in background for comparison. Rubber cracks considerably in this flex test but DuPrene does not. (E. R. Bridgwater.)

*Courtesy Industrial and Engineering Chemistry*

resistance to various conditions.<sup>104</sup> The following properties of DuPrene and its comparison with rubber are of note:

1. Compounds using DuPrene are not swelled nearly as much as corresponding rubber compounds are in petroleum distillates. While unsaturated compounds like oleic acid have almost the same swelling effect on DuPrene products as on rubber ones, the swollen DuPrene retains most of its toughness and tear-resistance. Carbon tetrachloride and aromatic hydrocarbons swell and cause some tendering of DuPrene, but the effect is not as great as on rubber.<sup>105</sup>
2. Overcuring DuPrene compounds does not ruin the aging properties as it does with rubber compounds.
3. Sulphur is not essential for the vulcanization of DuPrene.
4. Cements made by swelling DuPrene in appropriate solvents are better adhesives than those made from rubber.
5. Rubber compounds decline sharply in abrasion resistance with increasing temperature whereas DuPrene ones do not.
6. DuPrene is less permeable to gases than rubber.
7. It is more resistant to ozone.
8. It is not deteriorated by flexing in the way that rubber is. In one test the rubber sample broke through after 24 hours whereas the DuPrene after 80 hours showed no indication of failure. (See Fig. 46.)

<sup>103</sup> W. J. S. Naunton, M. Jones and W. F. Smith, *Trans. Inst. Rubber Ind.*, 1933, 9, 169. *Chem. Abs.*, 1934, 28, 2569. E. R. Bridgwater, *Ind. Eng. Chem.*, 1934, 26, 33; O. M. Hayden and E. H. Krismann, *Ind. Eng. Chem.*, 1933, 25, 1219.

<sup>104</sup> E. R. Bridgwater and E. H. Krismann, *Ind. Eng. Chem.*, 1933, 25, 280. O. M. Hayden and E. H. Krismann, *loc. cit.*

<sup>105</sup> F. Kirchhof (*Chem.-Ztg.*, 1934, 58, 542; *Brit. Chem. Abs. B*, 1934, 774) found that aromatic solvents caused greater swelling of  $\mu$ -chloroprene (as well as of chlorinated and vulcanized rubber) than aliphatic solvents.

9. Properly compounded DuPrene is affected hardly at all by 50 per cent sulphuric acid. Boiling for 4 days in 50 per cent sulphuric acid reduced the tensile strength from 191.6 kg./sq. cm. only to 80.8 kg./sq. cm.
10. Caustic soda and other common alkalis have practically no effect.
11. In nerve and snap it resembles natural rubber more than any other synthetic product and like natural rubber it gives an x-ray diffraction diagram.<sup>106</sup>
12. On the other hand, Whitby and Katz<sup>107</sup> found that the samples examined by them suffered a more serious fall in strength with rise of temperature than did samples of natural rubber.<sup>108</sup>

In compounding DuPrene, De Holczer<sup>109</sup> recommended the use of the plastic substance produced by Shinkle<sup>110</sup> through the action of ethylene dichloride on aromatic hydrocarbons of the type  $R-C_6H_4-R'$ , where R and R' represent hydrogen or alkyl radicals of more than one carbon. This mixture is less likely to scorch on milling and is resistant to hot lubricating oil at 150°C.

A mixture of chlorinated drying oils and polymerized chlorobutadiene has been suggested for use in a rubber composition to render it fireproof.<sup>111</sup> Hepp<sup>112</sup> advises using polymerized chloroprene as a binding agent.

Porous materials, i.e., leather, wood, cloth and tile, are said to be made resistant to water by impregnation with chlorobutadiene, followed by polymerization *in situ*.<sup>113</sup> The chlorodiene may be diluted with benzene, alcohol, acetone or carbon tetrachloride. The partially polymerized form has also been employed, either in solution, as an emulsion or in a spreading composition for surface coating. Drying oils, softeners and other resins, when incorporated, serve to enhance the desired properties. Oilproof paper, window shades, awning cloth and book-binding materials are included in the suggested uses.<sup>114</sup>

The homologues<sup>115</sup> of chloroprene do not polymerize so readily as chloroprene and the products are soft, plastic and sticky.<sup>116</sup>

The addition of aqueous hydrogen bromide to vinylacetylene in the presence of cuprous bromide leads to the formation of 2-bromo-1,3-butadiene or "bromoprene."<sup>117</sup> This compound may also be made directly from acetylene<sup>118</sup> by bringing the latter into contact with an aqueous solution of cuprous bromide and hydrobromic acid. Polymerization of bromoprene is somewhat more rapid than that of chloroprene, but the products are strictly analogous. Spontaneous polymerization yields first a plastic polymer ( $\alpha$ -polybromoprene) and then finally  $\mu$ -polybromoprene, which resembles vulcanized rubber but is more dense than the rubber

of  $\mu$ -polychloroprene. At elevated temperatures in the presence of antioxidants, a volatile, liquid  $\beta$ -polymer is formed.<sup>119</sup>

Chloroprene, bromoprene and other  $\beta$ -substituted dienes, i.e., 2-phenyl-1,3-butadiene, were treated by Carothers and Collins<sup>120</sup> with maleic acid and anhydride, fumaric acid and other compounds containing a reactive C-C double bond. The resulting products were stated to be serviceable as intermediates for the synthesis of dyes, perfumes and medicinal compounds.

#### OTHER HALOGEN DERIVATIVES OF ACETYLENE POLYMERS

Derivatives obtained by reacting divinylacetylene with sulphur monochloride have been reported to be synthetic drying oils, suitable for protecting articles from corrosion.<sup>121</sup> Vinylacetylene polymers may be made less liable to change due to the oxygen of the air by reducing their unsaturation. This may be accomplished by catalytic reduction<sup>122</sup> or halogenation.<sup>123</sup> Reaction is not carried so far that the products may not still be polymerized into rubber-like masses.<sup>124</sup> Condensation of the acetylene polymers with sulphuryl chloride<sup>125</sup> (SO<sub>2</sub>Cl<sub>2</sub>) has also been said to yield materials, some of which can be used as drying oils and in coating compositions.

By-products from the preparation of chloroprene, e.g., 4-chloro-1,2-butadiene, may be further chlorinated, and then treated with alkali to form unsaturated chlorinated hydrocarbons which are readily polymerized.<sup>126</sup> Thus, 4-chloro-1,2-butadiene (in carbon tetrachloride at -50°C.) is converted into 1,2,3,4-pentachlorobutane. Treatment of the latter compound with alcoholic potassium hydroxide gives 1,2,3-trichloro-1,3-butadiene which in turn, at 90°, is transformed into a soft non-plastic, non-rubber-like mass. Co-polymerization of 1,2,3-trichloro-1,3-butadiene and 2-chloro-1,3-butadiene, however, yields a softer, rubber-like body. Homologues of vinylacetylene may be produced<sup>127</sup> and polymerized. The polymers are used in the same manner as those of vinylacetylene itself. Mercury<sup>128</sup> and halogen substituted<sup>129</sup> vinylacetylenes are known also and these change into dark tars and solids on long standing. Several of the polymers are explosive. Blomquist and Marvel<sup>130</sup> obtained viscous tars and amorphous substances from the re-

action of the homologues of divinylacetylene with bromine and maleic anhydride, respectively.

Iodine reacts readily with acetylene, vinylacetylene and their homologues in liquid ammonia.<sup>121</sup> Methylvinyliodoacetylene made in this manner was a colorless liquid, but on standing in the presence of oxygen it became dark and viscous, eventually forming a black solid.

#### RESINOUS CONDENSATION AND POLYMERIZATION PRODUCTS OF ACETYLENE

Synthetic resins have been produced by Deutsch, Haehnel and Herrmann<sup>122</sup> by condensing acetylene with organic substances in the presence of salts of mercury or aluminum. If necessary, these catalysts were activated with acids or alkalis. The organic substances include aliphatic and aromatic hydrocarbons,<sup>123</sup> phenols, carboxylic acids and their esters. The products are either water-insoluble resins or substances of the cuprene type. For example, acetylene is introduced into an emulsion of mercury benzene sulphinate in glacial acetic acid, the mixture heated after absorption and then leached to yield a resin. By passing acetylene into an emulsion of amyl alcohol and mercury sulphate until absorption ceases, a liquid mass is obtained which, after decantation, can be used directly as a lacquer, or the resin can be isolated therefrom by distilling off the amyl alcohol. A cuprene-like substance is formed by introducing acetylene into an emulsion of aluminum chloride in dry benzene, mixing the product with water and steam-distilling off the benzene. Acetylene is passed into a heated mixture of hexane and mercury sulphate and the mixture heated for several hours. Removal of hexane by distillation yields a solid resin.

Bourgoin<sup>124</sup> made plastic substances applicable for electrical insulation by treating animal and vegetable fats mixed with calcium carbide with steam under pressure. Acetylene first forms which then reacts with the fatty substance. With cuprous chloride as a catalyst, Durand and Banos succeeded in condensing acetylene and carbon monoxide in pyridine solution to a black tar.<sup>125</sup> Quinone was identified as one of its constituents. Another resin from acetylene was obtained by Quilico and Freri by the action of fuming nitric acid on acetylene. They<sup>126</sup> obtained among other products an explosive substance,  $C_4H_2N_6O_7$ . This when dissolved in ethyl alcohol gives, with aniline, after evaporation of the solvent, a pitch-like mass.

#### RESINOUS SUBSTANCES FROM OTHER ACETYLENE HYDROCARBONS

Many of the higher homologues of acetylene are converted into resinous substances by polymerization either spontaneously or under the influence of heat, light, catalysts and silent electric discharges. Methylacetylene (propyne) changes to a white solid when exposed to a hot mercury-arc light.<sup>127</sup> By exposing 1-heptyne to the action of the silent discharge, Losanich<sup>127</sup> obtained along with liquid polymers

a dark-red, thick mass soluble in ether and benzene. Under similar conditions, 1-octyne gave a dark-red, soft mass, soluble in ether and benzene but insoluble in alcohol and having a molecular weight corresponding to a "nonaoctyne,"  $(C_8H_{11})_n$ .

When phenylacetylene is heated in a sealed tube for 23 hours at 230-240°C., it is converted into a tough, brown mass, soluble in ether. Alcohol precipitates an amorphous brown powder which, however, is readily soluble in most organic solvents.<sup>138</sup> When heated in a sealed tube with an aqueous solution of methylamine or ethylamine, phenylacetylene is converted into sym-triphenylbenzene. Under similar conditions, dimethylamine, trimethylamine, diethylamine and piperidine convert it into an oily substance. Aqueous ammonia and potassium hydroxide solutions likewise give tarry products.<sup>139</sup> Hunt and Turner<sup>140</sup> treated phenylacetylene with arsenious chloride and aluminum chloride. The resulting yellow liquid became black and viscous in 2 hours, but purification of the product yielded an amorphous yellow solid.

Diacetylene,  $CH\equiv C-C\equiv CH$ , is a very interesting hydrocarbon which is produced in small amounts during the electropyrrolysis of acetylene, methane, petroleum hydrocarbons and alcohol, and also in the thermal decomposition of acetylene, methane and other materials at very high temperatures. This hydrocarbon readily polymerizes above 0°C. with the formation of an insoluble brown mass which does not melt at 350°C. but explodes at higher temperatures.<sup>141</sup> When preserved in sealed tubes at 0°, in the absence of light, the hydrocarbon is transformed into a dark brown polymer, which explodes violently on contact with a hot wire.<sup>142</sup> Liquid products are formed from diacetylene at higher temperatures.<sup>143</sup> The analogous compound, dipropargyl<sup>144</sup> (1,5-hexadiyne) rapidly polymerizes to a solid hydrocarbon.

A number of hydrocarbons which contain both ethylenic and acetylenic bonds in other than the 1,3-position polymerize spontaneously to resins. Grignard and Lapayre<sup>145</sup> found that 1-phenylpenta-4-ene-1-yne,  $C_6H_5-C\equiv C-CH_2-CH=CH_2$ , resinifies on standing.

Hydrocarbons thought to be

were obtained by Lespieau and Journaud.<sup>146</sup> These hydrocarbons were formed by the action of allyl iodide on monosodium acetylide. When heated, they slowly polymerized. Likewise the pyrolysis of the methyl-substituted propargylphenyl ethers.

gave resins and tars.<sup>147</sup>

Tolane (diphenylacetylene) heated with 4,5-diphenylcyclopentenolone (anhydro-acetone-benzil) yielded a small amount of colorless crystals (m. p. 262-263°C) of tetraphenyl-benzene, together with a larger quantity of a resinous body.<sup>148</sup> Formation of the latter was reduced by carrying out the reaction in the absence of air.

## Chapter 9

# Polymerization of Hydrocarbon Olefins and Diolefins. Synthetic Rubber

The part played by polymerization in resin-forming reactions has already been discussed in Chapter 4. The present chapter deals solely with polymerization reactions involving unsaturated aliphatic and alicyclic hydrocarbons.<sup>1</sup> These compounds, as a class, including monolefins, diolefins and acetylenes,<sup>2</sup> possess an inherent tendency to polymerize. This tendency is not exhibited by typical saturated hydrocarbons, e.g., paraffins and cycloparaffins, nor by aromatic hydrocarbons.

Simple monolefins of the type  $R^1R^2C=CR^3R^4$ , in which  $R^1$ ,  $R^2$ ,  $R^3$ , and  $R^4$  are hydrogen atoms or alkyl groups, are capable of undergoing additive polymerization under the influence of heat, catalysts, the silent electric discharge, alpha-radiation, ultraviolet light, and similar energizing influences, but in most cases the products of such polymerization reactions are oily rather than resinous. The tendency of monolefins to undergo polymerization is greatly increased by the introduction of an electronegative group into the molecule at one of the carbon atoms in the ethylenic grouping. Accordingly, the so-called vinyl compounds (i.e. compounds of the type  $CH_2CX$ , where  $X$  is an electronegative atom or group), including styrene, vinylnaphthalene, vinyl halides, vinyl ethers and vinyl esters (see Chapters 11 and 51-53) are capable of undergoing very rapid polymerization, particularly in the presence of catalysts, with the formation of macromolecules possessing resinous characteristics.

In contrast to these readily polymerizable, negatively substituted olefins, the simple ethylene homologues are polymerized less easily and do not tend to form products of very high molecular weight except, perhaps, under very special circumstances. Thermal treatment of ethylene and its homologues has been found to yield simple polymers (the polymers themselves being olefins of double or treble the molecular weight of the parent hydrocarbon) but so many other reactions occur simultaneously that the true polymers are always present with other substances. At temperatures above 650°C. the main products of the pyrolysis of olefins are aromatic hydrocarbons and tars.

Since in most cases the monolefins yield only oily polymers, the diolefins are of more interest in the present discussion. Consequently the greater part of the chapter deals with the polymerization of the latter type of compound. Considerable study has been devoted to diolefins (particularly those containing conjugated double bonds) toward their conversion into products of high molecular weight. The object in view has been the production of a material which will meet the requirements demanded of a substance designed to replace natural rubber.

### POLYMERIZATION OF MONOLEFINS

Resinous substances, as well as oils, have been obtained by polymerization of the lower monolefins under the activating influence of the silent discharge. These

<sup>1</sup> Cf. the discussion of this subject by Carleton Ellis, "The Chemistry of Petroleum Derivatives," Chemical Catalog Co., New York, 1934.

<sup>2</sup> The polymerization of acetylene and its homologues and derivatives is treated in Chapter 8.

resinous products, however, are probably not true polymers of the original olefin but are formed as a result of a series of splitting and polymerization steps. By subjecting ethylene to a silent electrical discharge at  $-20^{\circ}\text{C}$ . for two weeks, Collie<sup>3</sup> obtained 10 grams of a product which boiled from below  $100^{\circ}\text{C}$ . to  $250^{\circ}$  and left a rubber-like residue. The latter had a composition closely agreeing with  $(\text{C}_6\text{H}_8)_x$ . An explanation of the mechanism of the initial polymerization reaction of ethylene in the presence of a high-frequency electric discharge is offered by Mignonac and Vanier de Saint-Aunay.<sup>4</sup> By circulating ethylene through the discharge at  $0-10^{\circ}\text{C}$ . and subsequently through a condenser cooled to  $-60^{\circ}$ , they were successful in polymerizing 90-95 per cent of the olefin. The product was found to be essentially a mixture of 1-butene and 1-hexene. The yield of 1-butene was greatly increased by cooling the condenser to  $-80^{\circ}$  and circulating the gas more slowly. By raising the condenser temperature, the product consisted essentially of 1-hexene. It would seem then, that two consecutive reactions were taking place.

These results were confirmed by Szukiewicz<sup>5</sup> who also experimented with a lower power discharge to obtain, among other hydrocarbons, butene, 1,3-butadiene and acetylene. Other investigators have noticed that hydrogen and methane as well as additional saturated hydrocarbons are simultaneously produced, so that a complex reaction mechanism must be postulated. In the products of the action of the silent discharge on isobutylene, Pryanischnikov and Demijanov<sup>6</sup> found both saturated and unsaturated hydrocarbons of varying degrees of molecular complexity. On prolonged exposure to the discharge, resinous substances of high molecular weight were formed, probably by fission and further polymerization. Upon subjecting trimethylethylene to the influence of a silent discharge, Losanitsch<sup>7</sup> obtained a brownish-yellow mass of the composition  $\text{C}_{10}\text{H}_{16}$  [i.e.,  $(\text{C}_5\text{H}_{10})_2 - 7\text{H}_2$ ] as well as colorless, liquid "diamylene" and "tetra-amylenes." In view of the nature of the resinous products it appears not unlikely that they are formed from diolefinic substances, produced by dehydrogenation of the simple olefinic polymers. By the action of a semi-corona discharge on various gases, including ethylene, Lind and Glockler<sup>8</sup> obtained considerable quantities of a resinous or gummy solid which was inert towards solvents and chemical reagents, except strong oxidizing agents. Exposure of 193 grams of ethylene to a discharge of 18,000 volts for 12.4 days gave 78.6 g. of this resinous solid and 40.1 g. of liquid condensation products.<sup>9</sup> Subjection of lower olefins to alpha-radiation and other energizing influences gives liquid and resinous condensation products similar to those obtained with the silent discharge.<sup>10</sup>

A number of catalysts are very active in promoting the polymerization of ethylene and its homologues to substances of varying degrees of molecular com-

plexity. Among the more important catalysts, the following may be mentioned: concentrated sulphuric acid, hydrogen fluoride, ozone,<sup>11</sup> aluminum chloride,<sup>12</sup> boron trifluoride, zinc chloride, stannic chloride, activated hydrosilicates such as floridin, and anhydrous metallic halides activated by the addition of finely divided metals. The products of reaction consist of oils ranging from volatile liquids to viscous syrups. Low temperatures favor the formation of very high-molecular-weight materials. The high-boiling oily polymerization products obtained under the influence of aluminum chloride and boron trifluoride have been suggested as lubricating oils.<sup>13</sup> Brown, viscous and sticky liquids were obtained by Stanley<sup>14</sup> by the polymerization of ethylene under pressure in the presence of aluminum chloride at 0-10°C. and these possessed molecular weights represented by the formula  $(C_2H_4)_x$ , where x was as high as 40 or 50. Monolefins have been polymerized to yield products of high molecular weight by using inorganic volatile halides as catalysts.<sup>15</sup> For example, boron fluoride may be bubbled through isobutylene cooled to -80°C. Additional catalysts, prepared by charging boron fluoride with hydrogen fluoride, phosphorus tri- or pentafluorides and aluminum chloride have been recommended. According to Waterman, Over and Tulleners,<sup>16</sup> the polymerization of isobutylene, catalyzed by aluminum chloride, is violent and sometimes even explosive when carried out at -78°C. Under these conditions a pale-yellow polymerization product was isolated whose molecular weight was estimated at 600-700. The polymer is described as very tough and sticky with a capacity for being drawn into threads. An interesting polymerizing agent is floridin (or Florida earth), since this material appears to polymerize the lower olefins to a complex mixture of liquids, which still contain a double bond of unsaturation. In the presence of floridin, isobutylene<sup>17</sup> polymerizes even at -80°C., but more rapidly at room temperature, to yield a mixture of polymers, some of which are very viscous and of high molecular weight. Thus, 71 per cent of the polymers obtained by bringing isobutylene in contact with floridin at room temperature boiled above 185°. Staudinger and Brunner<sup>18</sup> have examined isobutylene polymerized in the presence of floridin, first at -80°C. and then at 5°C. They separated the resulting mixture, by distillation and subsequent extraction with alcohol, into triisobutylene, pentaisobutylene, and a polyisobutylene. The latter was subsequently purified by precipitation from an ethereal solution by the addition of alcohol. The product, so obtained, was a viscous mass with a density 0.9 and a mean molecular weight of 1600 in benzene. The material was stable toward warm potassium permanganate and nitric acid but absorbed bromine to the extent of 50 per cent of

<sup>11</sup> Ozone reacts with ethylene hydrocarbons forming ozonides which readily polymerize in some cases to solid gummy or glassy substances. The explosive character of ozonides is such as to deter usage in the synthetic resin field. The subject of ozonides has been summarized by C. D. Harries, *Ann.*, 1905, 343, 311; 1910, 374, 283; 1913, 390, 236; 1915, 410, 1; *Chem. Abs.*, 1910, 4, 2633; 1912, 6, 2154; 1915, 9, 2877. See also R. Koetschau, *Z. angew. the theoretical amount for one double bond, in  $(C_6H_8)_n$ . Its solubility, viscosity, and physical properties were very similar to those of a hemicolloidal hydorrubber, obtained by the hydrogenation of natural rubber or rubber latex. (See Chapter 54.)

Sulphuric acid converts many of the simple monolefins to only polymers but it also exerts a splitting action on these polymers so that both saturated and highly unsaturated hydrocarbons are formed.<sup>19</sup> None of the simple monolefins give rise to resinous substances similar to the products formed from vinyl compounds, cumarone or indene under the influence of concentrated sulphuric acid. According to Friese,<sup>20</sup> however, cyclohexene and concentrated sulphuric acid react vigorously to form a dark resin, insoluble in water. A resinous product was obtained by Nametkin and Abakumovskaja<sup>21</sup> by reaction of cooled sulphuric acid (sp. gr. 1.84) on one-third of its volume of cyclohexene.<sup>22</sup> Isobutylene, trimethylethylene and similar monolefins are converted into their simple di- and trimers by treatment with sulphuric acid of about 80 per cent concentration, or even lower.<sup>23</sup> However viscous or solid polymers of high molecular weight are obtained by the action of liquid sulphur dioxide on isobutylene.<sup>24</sup> The reaction is carried out in sealed tubes and catalyzed by sunlight to yield compounds having the empirical composition  $(C_4H_8SO)_x$ . Propylene and amylene are said to give solid polymers under similar conditions.

Zelinsky and Borisov<sup>25</sup> treated cyclohexene with oxygen in the absence of catalyst for 151 days and obtained, after removal of unchanged cyclohexene, a resinous reddish-yellow mass, which analysis showed to be the peroxide. However, the constitution of the resinous substance is not known. Studies on the polymerization of cyclohexene have been made by Waterman and co-workers.<sup>26</sup> With pentane as a liquid diluent and aluminum chloride as catalyst polymerization was only slight at 40°C. However, at 70°, treatment with 6-7 per cent aluminum chloride for 7 hours resulted in more than 50 per cent conversion of cyclohexene into high-molecular oily compounds. Although at -78°C. cyclohexene exhibited practically no polymerization in the presence of pentane and aluminum chloride, the simultaneous addition of hydrochloric acid and aluminum chloride under these conditions resulted in a rapid reaction, yielding monochlorocyclohexane and a mixture of monochloro-polycyclohexyl compounds.

The effect of sulphur dioxide upon the polymerization of cyclohexene has been investigated by Marvel, Frederick and Cogan.<sup>27</sup> The product obtained by allowing cyclohexene, liquid sulphur dioxide and an oxidizing catalyst to stand in a pressure flask at room temperature is a hard, brittle, white, amorphous solid. The degradation products obtained by treating this substance with non aqueous alkali indicate that it is a polymeric sulphone whose most probable structure is

A halogen-containing derivative can be prepared by treating the polysulphone with chloroacetyl chloride. Halogen analyses and molecular-weight determinations carried out with the derivative indicate that the value of  $n$ , in the above formula, is about 39. Experiments<sup>28</sup> carried out at  $-30^\circ\text{C}$ . with cyclohexane and sulphur dioxide in the presence of oxygen yielded a polymer with the approximate formula  $(\text{C}_6\text{H}_9\text{SO}_2)_x$ . When no oxygen was used the material obtained had the formula  $(\text{C}_6\text{H}_8\text{SO}_2)_x$ .

Resinous and gummy polymerization products have been obtained from monolefins by Wagner-Jauregg's<sup>29</sup> so-called "additive heteropolymerization" process in which two unlike units of low molecular weight and containing ethylene linkages may undergo addition and polymerization simultaneously. In this type of reaction maleic anhydride, which has no tendency to polymerize but which shows a marked additive capacity, has been used exclusively as a constant member of such mixtures. When sym-diphenylethylene and maleic anhydride are boiled in xylene, a white amorphous, infusible substance is formed. The examination of the resin would seem to indicate a product composed of definite units, such as

in which  $x$  corresponds to an average of 15.

Viscous, gummy polymers resulted when anilene and styrene were heated with maleic anhydride. (See Chapters 11 and 40). In general, it may be said that the nature of substituent groups, proper selection of solvents, and steric hindrance affect the ease of heteropolymerization.

#### POLYMERIZATION OF DIOLEFIN HYDROCARBONS

Of the diolefin hydrocarbons, only those containing a conjugated system of double bonds and including butadiene and its homologues as well as cyclic diolefins of the type of cyclopentadiene, need be considered. These conjugated diolefins exhibit a very pronounced tendency to polymerize to resinous or rubber-like polymers, as well as to lower liquid polymers, under a wide variety of influences. Other diolefinic hydrocarbons including 1,2-diolefins (or allenes), 1,4-, 1,5-, and 1,6-diolefins do not polymerize so readily or as profoundly as the conjugated dienes.

In the polymerization of butadiene and its simple homologues, products of widely varying properties are obtained depending upon the experimental conditions. Besides liquid cyclic dimers and trimers, the high-molecular-weight amor-

<sup>28</sup> W. F. Seyer and E. G. King, *J.A.C.S.*, 1933, 55, 3140.

<sup>29</sup> T. Wagner-Jauregg, *Ber.*, 1930, 63, 3213; *Chem. Abs.*, 1931, 25, 2418.

phous polymers, simultaneously formed, may be roughly separated into several qualitatively different species of polymeric mixtures.

The aim of all endeavors to polymerize conjugated diolefins to high-molecular-weight polymers has been the production of a synthetic rubber capable of meeting all the complex technical requirements of natural rubber, particularly the ability to be vulcanized. In spite of nearly half a century of scientific and industrial investigation in this field, the problem of the successful synthesis of true rubber on a technical scale is still unsolved. For special purposes, however, the synthetic rubber-like polymers of the conjugated diolefins may find industrial application.

**Polymerization of Butadiene and Its Homologues.** Natural rubber is supposed to consist of a mixture of polymeric hydrocarbons whose general configuration can be written.<sup>30</sup>

The rubber molecule consists, therefore, of a long chain of units composed of many hundreds of isoprene molecules  $\begin{array}{c} \text{CH}_2=\text{C}-\text{CH}=\text{CH}_2 \\ | \\ \text{CH}_3 \end{array}$  combined by a process of

1,4-addition.<sup>31</sup> Accordingly the most obvious raw material for conversion into rubber-like substances by polymerization is isoprene itself. Isoprene possesses an unusual tendency to polymerize and in fact was the first conjugated diolefin to be transformed into a rubber-like material.<sup>32</sup>

However, it is by no means the only hydrocarbon of this type capable of undergoing such polymerization. Both butadiene<sup>33</sup> and 2,3-dimethylbutadiene<sup>34</sup> were found to polymerize under the influence of heat and catalysts but not quite so readily as isoprene. Although the data available on the extent to which the tendency of butadiene homologues to polymerize to rubber-like and resinous polymers are far from complete, certain facts are now well established. Of the butadiene homologues containing one methyl group, both 1- and 2-methylbutadienes (piperylene and isoprene) are polymerizable to caoutchouc-like substances; but, of the disubstituted members, only 2,3- and 1,4-dimethylbutadienes undergo this condensation. Fisher and Chittenden<sup>35</sup> encountered difficulty in polymerizing 1,2-dimethylbutadiene on account of the slowness of reaction. According to the observation of Kyriakides,<sup>36</sup> the 1,1-dimethyl compound is polymerizable, although Harries<sup>37</sup> states that the change occurs only with difficulty. Furthermore, 1,2,3,4-tetramethylbutadiene shows no tendency to polymerize.<sup>38</sup> It appears that methyl substituents in butadiene diminish the ease of polymerization and that methyl substitution in the terminal positions has a more unfavorable effect on polymerization tendency than substitution in the middle positions.<sup>39</sup> The intro-

<sup>30</sup> Thermal decomposition of natural and butadiene rubber, at lower temperatures than in the ordinary cracking process and catalyzed by aluminum chloride, yields a gasoline-like fluid high in aromatic compounds. In neither instance was isoprene obtained. This may indicate the formation of aromatic compounds during the polymerization of butadiene hydrocarbons. N. D. Zelinski and N. S. Kozlov, *J. <sup>39</sup> The velocity of polymerization of various diolefins is discussed by E. M. Gapon, *J. Russ. Phys.-Chem. Soc.*, 1930, 62, 1385; *Chem. Abs.*, 1931, 25, 2968; *J. Gen. Chem. (Russia)*, 1931, 1, 496, 765, 779;

duction of phenyl groups into the butadiene system is said by Whitby and Gallay<sup>40</sup> to favor the formation of dimers but to inhibit further polymerization.<sup>41</sup> However, the polymerization does not stop at the dimer stage if the proper catalysts are employed. Staudinger and Ashdown,<sup>42</sup> using stannic chloride as a catalyst, were able to prepare polymers of 1-phenylbutadiene having an approximate molecular weight of 1500. Benzene or carbon tetrachloride is an appropriate solvent for the reaction.

The substitution of a halogen for a hydrogen atom in the butadiene system has given very interesting results. 2-Chlorobutadiene, or chloroprene, on standing undergoes complete transformation to rubber-like polymers in a few days, while 2-bromobutadiene polymerizes even more rapidly.<sup>43</sup> The ease and nature of polymerization depends not only upon the presence of halogen, but also upon its position in the molecule. For example, Staudinger<sup>44</sup> and his co-workers found that mixtures of monobromoisoprenes, obtained by treating 1,4-dibromo-2-methyl-2-butene with sodium methoxide, would not polymerize in the cold and decomposed when heated. Similarly a dibromoisoprene (b. p. 78-83°C. at 12 mm.), produced by splitting out of 2 molecules of hydrogen bromide from isoprene tetrabromide, decomposed upon heating instead of polymerizing. Muscat and Northrup<sup>45</sup> reported a dark resinous mass from the polymerization of 1-chlorobutadiene.

Resinous products resembling rubber or celluloid and capable of being rolled into thin sheets have been obtained by the polymerization of dichlorobutadiene.<sup>46</sup> The latter is made by splitting off 2 mols of hydrochloric acid from tetrachlorobutane with alcoholic potash. The polymerization is carried out in a closed vessel at 20-50°C., oxygen being excluded. Insolubility in benzene is imparted to the final product by a heat treatment at 140-150° for 10 minutes.

In the polymerization of butadiene and its homologues, several types of polymers are formed depending on the conditions. These include liquid dimers and trimers, pasty or plastic polymers, tough rubber-like substances, and also granular masses. There is some disagreement among different investigators as to the exact nature of the dimer formed, although it is believed that the product is a monocyclic compound. Experiments dealing with the thermal polymerization of isoprene have indicated that the mechanism of the reaction is essentially a bimolecular association process.<sup>47</sup> However, regarding the higher polymers, the constitution is still quite obscure. In the preparation of synthetic rubber, the liquid polymers contaminate the product and may be removed by treating the mass with such powdered absorbents as activated carbon or silicon dioxide.<sup>48</sup> The constitution of the synthetic-rubber polymers is still unclarified.

The influence of structural modifications on the polymerization of butadiene derivatives with respect to rate of polymerization and the character of the polymers formed is summarized in Table 22.

\* W. H. Carothers, *Ind. Eng. Chem.*, 1934, 26, 30.

The estimated speeds are based on calculated unimolecular reaction velocity constants. The data from which the constants are derived suffer from a very large factor of uncertainty owing to the fact that, for dienes, the rate of polymerization varies considerably with the history of the sample and with conditions (amount of exposure to light and air) which are not specified or controlled in all of the experiments. These uncertainties are, however, thought to be insufficient to affect the order of magnitude of the indicated numbers.

<sup>b</sup> The constant taken for isoprene was 0.0000048 (in hours) and was derived, by extrapolation, from data presented by G. S. Whitby and R. N. Crozier, *Can. J. Research*, 1932, 6, 203; *Brit. Chem. Abs.* A, 1932, 361.

**Butadiene Sulphones.** By treating isoprene in an ethereal solution with sulphur dioxide,<sup>40</sup> crystalline isoprene sulphone, melting at 63-63.5°C., may be obtained in a yield of 60 per cent. The following constitution has been assigned to the compound:

Isoprene sulphone readily takes up bromine (in carbon tetrachloride) to form the dibromide melting at 127°C. Upon treating the dibromide with sodium hydroxide in a methyl alcohol solution, a polymer of 2-methyl-2,3-butadiene

<sup>40</sup> E. Eigenberger, *J. prakt. Chem.*, 1930, 127, 307; *Chem. Abs.*, 1931, 25, 276.

sulphone  $<1,4>$  is formed. The allene nature of the polymer was assumed from its degradation products and because of its ease of oxidation and general unsaturated nature except towards bromine. Subsequently Eigenberger<sup>50</sup> found that when isoprene sulphone was treated with dilute aqueous or alcoholic potassium hydroxide in the light of a quartz lamp, an isomeric isoprene sulphone B, melting at 79°C., could be recovered. The alkali is an essential factor, for the reaction will not take place in the presence of the radiation alone. Isoprene sulphone gave, upon treatment with potassium in dry ether, the potassium salt of 3,6-dimethyl-2,4-octadiene-1,8-disulphinic acid. The product was characterized by its pronounced instability and tendency toward polymerization. The polymerization product, in this case, was an ether-insoluble, amorphous compound, soluble in ethyl acetate.

**Liquid or Oily Polymers.** Liquid polymers are produced from butadiene hydrocarbons under a variety of circumstances but usually under the influence of heat and in the absence of active polymerizing agents. Most of these liquid polymers are cyclic unsaturated hydrocarbons and are by-products of the rubber syntheses, i.e., they cannot be polymerized further to rubber-like substances. However, the dimers of 2,3-dimethylbutadiene are polymerized rapidly in the cold under the influence of antimony pentachloride or stannic chloride, yielding high-molecular-weight polymers which may be isomers of rubber.<sup>51</sup> Viscous and liquid polymers have also been obtained by carrying out the polymerization in the presence of boron trifluoride<sup>52</sup> and aluminum chloride.<sup>53</sup> Experiments have indicated that the dimer of butadiene, obtained by heating that hydrocarbon under pressure, is vinylcyclohexene.<sup>54</sup>

When isoprene is heated to 80°-90°C. for several days, or in sealed tubes at 150°C. for 6 to 7 days, liquid polymers as well as resinous substances are formed. At least two dimers are present in this mixture: namely, dipentene and  $\beta$ -myrcene or diprene, the formulas of which are:<sup>55</sup>

According to Whitby and Crozier,<sup>56</sup> the polymerization of pure isoprene and

dimethylbutadiene at temperatures of 10-145°C. does not afford, in either case, any dimer which is polymerizable to caoutchouc. The products isolated by these investigators were only cyclic dimers and are not regarded as intermediates in the formation of rubber-like substances. In the polymerization of 2,3-dimethylbutadiene<sup>67</sup> under similar conditions, much less oily materials and a higher proportion of rubbery polymers were formed than in the case of isoprene. The ratio of oil to rubber from a given diene is approximately constant in different periods of polymerization at a given temperature. Lebedev and Mereshkovski<sup>68</sup> consider that the dimer of 2,3-dimethylbutadiene possesses the constitution:

In the case of chloroprene, the formation of the volatile, oily  $\beta$ -polychloroprene<sup>69</sup> is favored by polymerization at elevated temperatures, e.g., at 60°C., in the absence of air and in the presence of antioxidants, which suppress the production of rubber-like polymers.  $\beta$ -Polychloroprene probably consists of cyclic dimers and other simple polymers. (See Chapter 8.)

**Rubber-like Polymers.** The formation of rubber-like or balata-like polymers from butadiene, isoprene, or 2,3-dimethylbutadiene proceeds slowly when these substances are warmed, or when they are allowed to stand at ordinary temperature in contact with catalysts.<sup>69</sup> Chloroprene, however, polymerizes spontaneously at ordinary temperatures and with a much greater speed. As previously stated, several qualitatively different types of material are produced depending upon the conditions. The first step of the process is probably the formation of long polymeric chains, consisting of units of the diolefin united by 1,4- addition. A consideration of the kinetics and general characteristics of these reactions suggests that the formation of rubbery or similar high-molecular-weight polymers from diolefins is the result of a chain reaction. This postulate is based on evidence indicating that such reactions are usually unimolecular,<sup>71</sup> are catalyzed by a wide variety of substances capable of acting as "trigger" molecules<sup>72</sup> and that they are inhibited by antioxidants as well as certain other substances. It follows, then, that the reaction is initiated by an activated diolefin molecule or by some other molecule acting as a "trigger."<sup>73</sup> Under conditions which inhibit the propagation

<sup>72</sup> J. A. Christiansen and H. A. Kramers (*loc. cit.*) have proposed the theory that chain reactions are initiated by the action of an activated molecule of high energy content, the so-called "trigger" molecule. The activated molecule is believed to react either unimolecularly or with another molecule in such a way that the products must have the initial energy of activation plus the additional energy of reaction if it is exothermic. According to this mechanism it is possible for the "trigger" molecules to activate other molecules by transferring this energy through subsequent collisions. See also H. W. Starkweather and G. B. Taylor, *J.A.C.S.*, 1930, **52**, 4708.

<sup>73</sup> W. Chalmers, *Can. J. Research*, 1932, **7**, 113; *Chem. Abs.*, 1932, 26, 5480. W. H. Carothers, et al., *J.A.C.S.*, 1931, **53**, 4216.

of a chain mechanism, rubbery polymers are either not formed, or their formation is suppressed, and only lower polymers are produced. It appears, therefore, that as a result of the chain reaction, high-molecular-weight polymers somewhat resembling natural rubber are obtained. In natural rubber the isoprene units seem to be arranged in a very symmetrical manner, i.e., they are united regularly in 1,4-1,4 . . . order. However, in synthetic rubber there is good reason<sup>64</sup> to believe that a more or less irregular arrangement of isoprene-molecule units takes place; that is, arrangements such as 1,4-4,1 . . . and 4,1-1,4 . . . occur. In order to duplicate the properties of natural rubber, the isoprene would need to be polymerized under conditions leading to a regular arrangement of units in the polymer molecule. In view of the great complexity of the reaction, it is obvious that such a condition is enormously difficult of fulfillment and would necessitate a very special combination of circumstances. However,  $\mu$ -polychloroprene yields a sharp x-ray diffraction pattern, like natural rubber, but the same property is absent<sup>66</sup> from other synthetic rubbers. This indicates that a more regular arrangement of chloroprene units is present in the polychloroprene molecule, possibly owing to the orientating influence of the halogen atom. Irrespective of the manner in which the units are combined in synthetic rubber, the molecular weight and chain length approach very closely those of plasticized natural rubber.<sup>66</sup>

In other respects, moreover, the synthetic rubber-like substances from isoprene may display irregularities not exhibited by natural rubber. The molecules may be coiled into spirals rather than rigidly extended. Also, there is a possibility of geometrical isomerism so that irregular arrangements such as *cis-cis-cis*— or *trans-trans-trans*— . . . may exist. Finally, there is a possibility of cross-linking of chains at occasional points to produce a structure of the type:

Since each isoprene (or diolefin) unit in the polymeric complex still has one unsaturated linkage, cross-linking of several polymeric macromolecules can take place until finally all these points of unsaturation are fully saturated and a complex polycyclic material will be formed. It seems highly probable that such "cyclorubbers" are actually formed during the polymerization of diolefins in the presence of various catalysts. For instance, the granular, cauliflower-like varieties of synthetic rubbers which are obtained by very slow polymerization, and also in the presence of sodium, are probably formed by a cross-linking of polymer chains, i.e., they are likely to be cyclic in structure. Such materials<sup>67</sup> are tough, nonplastic, difficult to mill, and show little resemblance to natural rubber.

**Conditions for the Conversion of Diolefins into Rubber-like Polymers.** The earlier workers on the polymerization of isoprene employed hydrochloric acid and nitrosyl chloride as condensing agents. Later, isoprene was found to be rapidly converted into rubber-like substances under the influence of ordinary light,<sup>68</sup> ultraviolet light,<sup>69</sup> and the silent electric discharge,<sup>70</sup> and it has

<sup>69</sup> C. Harries, *Ann.*, 1913, 395, 266; *Chem. Abs.*, 1913, 7, 1983. I. Ostromislensky, *J. Russ. Phys.-*

been stated that these influences are superior to all chemical catalysts with the exception of oxygen or certain oxygenated substances. In 1910, Harries noted that isoprene could be polymerized to rubber by heating it with glacial acetic acid in a sealed tube at 100°C. The product could be vulcanized and was evidently superior to any previously prepared. About the same time, Matthews and Strange<sup>71</sup> found that metallic sodium was a catalyst for the conversion of isoprene into rubber. The use of sodium in an atmosphere of carbon dioxide was also developed by the Badische Co. Nevertheless, though isoprene is converted at 60°C. in from 50 to 100 hours almost quantitatively into caoutchouc, this material possesses properties different from those of synthetic products prepared in other ways;<sup>72</sup> that is, the sodium-polymerized product is probably differently cyclized by cross-linking of several polymer-chains.

Hofmann<sup>73</sup> and his collaborators reported that pure isoprene could be polymerized by mere heat treatment to give a material capable of being cured. This was probably the first time that a synthetic product was developed corresponding in any degree with the technical requirements of rubber. The heat-treatment process was utilized successfully for the manufacture of rubber from 2,3-dimethylbutadiene during the World War.

Harries<sup>74</sup> outlined three methods of polymerizing butadiene and its simple homologues: (1) heat treatment, by itself or in conjunction with glacial acetic acid, for several months at 60-100°C., (2) heating, or allowing the hydrocarbon to stand in the presence of metallic sodium in an atmosphere of carbon dioxide, and (3) heating with peroxides, especially benzoyl peroxide. Since that time a large number of catalysts have been developed for accelerating or controlling the polymerization of diolefins. Also, the method of polymerizing diolefins in aqueous emulsion has been developed. Even before the War the chemists of the Bayer Co. had learned that both the yield and the properties of isoprene rubber were improved by carrying out the polymerization in a sealed vessel in the presence of an aqueous preparation of a protein. The polymerization of emulsified diolefinic hydrocarbons presents one of the satisfactory methods for the synthesis of rubber-like materials on a technical scale.

#### CATALYSTS FOR THE SYNTHESIS OF RUBBER

Though the usual active polymerizing agents such as concentrated sulphuric acid, aluminum chloride,<sup>75</sup> stannic chloride, antimony halides,<sup>76</sup> boron trifluoride,<sup>77</sup> and titanium tetrachloride,<sup>78</sup> are known to convert isoprene and similar 1,3-diolefins

into polymers, the products are stated to be of little value as rubber substitutes. A possible explanation of this fact is that cross-linking of the polymeric chains proceeds very rapidly and a complex polycyclic structure is produced with properties unlike those of ordinary rubber.<sup>70</sup> Aryl diazonium fluoborates<sup>80</sup> are said to be quite effective in catalyzing the polymerization of indene, styrene, cyclopentadiene, phenyl butadiene, pinene, isoprene and other similar compounds. The catalytic influence of peroxides, per-acids, oxidized substances and oxygen itself on the polymerization of all types of unsaturated substances including styrene and isoprene has been recognized for many years.<sup>81</sup> Organic peroxides, metal oxides, per-salts,<sup>82</sup> and the products obtained by ozonizing isoprene<sup>83</sup> have all been proposed as catalysts for the conversion of isoprene into rubber.<sup>84</sup> Conant and Tongberg<sup>85</sup> have shown that a partially ozonized sample of isoprene polymerized more rapidly under high pressure than did unozonized isoprene. The polymerization of 2,3-dimethylbutadiene is accelerated at room temperature by the presence of 4 per cent or less of ozonized diisobutylenes.<sup>86</sup> From experiments on isoprene and dimethylbutadiene in the presence of oxygen, Staudinger and Lautenschläger<sup>87</sup> conclude that polymerization is accelerated by autoxidation and that the active polymerizing catalyst is probably a primary peroxide (not isolated) rather than the isolated polymerized peroxides. In the polymerization of styrene, however, oxygen is less active than benzoyl peroxide and diisobutylene ozonide is even more active as a catalyst than the latter.<sup>88</sup>

The application of metallic sodium as a catalyst for the polymerization of 1,3-dienes has already been described. However, according to Zelmanov and Shalnikov<sup>89</sup> the adoption of colloidal sodium is a decided improvement over the old method. Solid polymers from butadiene were obtained in 2-36 hours at 10-15°C. using only 0.001 to 0.3 per cent of sodium as the catalyst. The catalyst was prepared by condensing sodium and butadiene on a cooled surface, simultaneously. Various derivatives of the alkali metals, including sodium amide or alkali metal alkyls,<sup>90</sup> have been used for this purpose. Diazoaminobenzene is said to catalyze the polymerization of butadiene obtained from petroleum fractions.<sup>91</sup> A number of other apparently unrelated materials have been suggested, including glycerol, starch and urea.<sup>92</sup>

#### COMMERCIAL ATTEMPTS TO SYNTHESIZE RUBBER

Attempts have been made to develop the synthesis of rubber on a commercial scale, especially in Germany, but so far without success. The low price of natural

<sup>70</sup> The production of resins from nuxtures of diolefins and olefins under the influence of anhydrous aluminum chloride is considered later.

rubber at the present time would appear to render impossible a successful rubber synthesis unless the synthetic product possessed special properties and was particularly adaptable for certain purposes. Before the World War, attempts to convert isoprene into a technical rubber product were made by the Bayer Co. and others, but, although several commercially practicable syntheses of isoprene from acetylene, or amyl alcohols, were developed, no real technical advance resulted. During the War, a process was developed in Germany by the Bayer Co. whereby about 150 tons of dimethylbutadiene rubber (methyl rubber) were made per month with a total production of 2350 tons.<sup>93</sup> The 2,3-dimethylbutadiene was synthesized from acetylene via acetone and pinacol. A small amount of a somewhat unstable methyl rubber was later prepared from 2,3-dimethylbutadiene by the Badische Co. using the sodium-carbon dioxide method. However, most of the methyl rubber was prepared by heat treatment and two types of product were obtained; namely, methyl rubber W and methyl rubber H.

FIG. 47.

Methyl Rubber, a Product Obtained by the Polymerization of Dimethylbutadiene.

Courtesy G. S. Whitby

**Methyl Rubber W.** Crude methyl rubber W<sup>94</sup> was produced by keeping liquid 2,3-dimethylbutadiene in large double-walled vessels for about five months at 70°C. The entire contents of the vessel were thereby converted into a tough, rubber-like, greenish yellow, translucent mass. This material was difficult to work on the mill and required large amounts of organic or inorganic fillers. Its use in soft-rubber goods was suggested.

**Methyl Rubber H.** The so-called "methyl rubber H" was made by filling thin-walled tin-plate vessels about one-third full of dimethylbutadiene and storing them for about two months at 30°C. To hasten the process the batch was inoculated with previously polymerized material.<sup>95</sup> The product was a white, porous, cauliflower-like mass with little resemblance to raw rubber. (See Fig. 47.) On a hot mill the substance first crumbled but soon milled to a smooth sheet, still retaining a certain dryness and granular consistency.

According to Weil,<sup>96</sup> these synthetic products possessed decided disadvantages when compared with natural rubber. For example, they did not show a true

<sup>93</sup> It. Weil, *Ind. Eng. Chem.*, 1926, 18, 1174.

<sup>94</sup> The history of dimethylbutadiene synthetic rubber research has been reviewed by V. A. Getling and N. V. Zhdanova, *Sintet. Kauchuk*, 1933, 5, 15; *Chem. Abs.*, 1934, 28, 3615.

<sup>95</sup> Methyl rubber H in properties and autocatalytic mode of formation appears to be closely analogous to the  $\omega$ -polychloroprene described by W. H. Carothers, I. Williams, A. M. Collins and J. E. Kirby, *J.A.C.S.*, 1931, 53, 4214. See Chapter 8.

<sup>96</sup> R. Weil, *loc. cit.*

plasticity, lacked elasticity, were deficient in adhesive strength, and showed instability, although the latter defect could be overcome by the addition of preservatives such as 1,8-diaminonaphthalene. Methyl rubber, particularly the H variety, found successful application in electrical insulation, especially in the cable industry, in the manufacture of steam- and air-brake hose for railways, and for insulation in batteries. For use in tire manufacture, these synthetic products were not very satisfactory, being lacking in elasticity.<sup>97</sup>

More recent developments in the problem of synthesizing rubber include the work of the I. G. Farbenindustrie A.-G. in Germany, and E. I. du Pont de Nemours & Co. in the United States. It has also been reported that a synthetic-rubber industry is being organized in Russia.<sup>98</sup> In the production of artificial rubber as undertaken by the I. G. Farbenindustrie A.-G., isoprene<sup>99</sup> constitutes the raw material. The synthesis of the latter is indicated in the following series of reactions:

The resulting isoprene is polymerized to rubber by heating it with water, or caustic alkali, at 100°C. in the presence of acids, alkali metals, oxidizing agents, emulsifiers and a buffer system of  $\text{pH}$  4.8-5.0.

A product bearing the name of Polynit is prepared from butadiene by sodium polymerization or, better, by warming an emulsion of that hydrocarbon with ammonium oleate. The polymerized product is baked at 150°C. for two hours giving an infusible material insoluble in all solvents and chemically quite resistant.<sup>100</sup>

<sup>97</sup> For the vulcanization of methyl rubber, see G. S. Whitby and M. Katz, *Can. J. Research*, 1932, 6, 398; *Chem. Abs.*, 1932, 26, 4204.

<sup>100</sup> Butadiene may be prepared by the dehydration of 1,3-butylene glycol in the presence of alum or a mixture of calcium and sodium phosphates at 240-250°C. The glycol is synthesized from acetylene via acetaldehyde and aldol. See British P. 291,748, 1928, to I. G. Farbenind. A.-G.; *Brit. Chem. Abs.*, B, 1929, 886. French P. 659,314, 1928; *Chem. Abs.*, 1929, 23, 5197.

The synthesis of rubber and a vulcanized rubber-like substance ( $\alpha$ - and  $\mu$ -polychloroprenes) from 2-chlorobutadiene has been described in Chapter 8.

A complete survey of the vast literature of synthetic rubber production might easily occupy several volumes.<sup>101</sup> In the following abbreviated account, the main trend of investigation is summarized as concisely as possible. Three main methods of polymerizing butadiene and its simple homologues, particularly isoprene and 2,3-dimethylbutadiene, have been developed: (1) heat-polymerization usually in the presence of an oxygen or other catalyst; (2) alkali-metal polymerization; and (3) polymerization in the form of an emulsion and usually in the presence of catalysts. The latter method yields a synthetic latex capable of being precipitated to form a rubbery mass.

In connection with the polymerization of diolefins to substances resembling rubber, certain mechanical details relating to temperature control, handling of the reactants or products and type of apparatus employed, seem to be worthy of brief mention inasmuch as they contribute a great deal to the success of the operation. An effective device for avoiding the deleterious action of excess heat upon unreacted diolefins<sup>102</sup> consists of a vessel called a "moderator." The vessel contains no polymerizing agent. The device is connected to the reaction vessel in such a way that the excess heat liberated during the reaction causes the diolefin to distil over into the "moderator." When the reaction has subsided, the diolefin is returned to the reaction vessel. To facilitate the removal of the polymerization products from the vessel, various coatings and linings have been suggested.<sup>103</sup> Readily removable materials such as paper, cardboard, textile fabrics and leather are advocated. These materials may be coated with a nitrocellulose or gelatin varnish. Waxes, bitumens, water glass and polymers of diolefins are also said to be of assistance in removing the reaction-mass. Double-walled vessels for "sodium" polymerizations have been described<sup>104</sup> in which the hydrocarbons may come in contact with the sodium through connecting holes of at least 2 mm. diameter. Polymerization in the presence of alkali or alkaline earth metals is favored by metal vessels having smooth, highly polished inner surfaces free from edges.<sup>105</sup>

**The "Emulsion" Method.** In this process, which is probably the most important of the three methods outlined above, the conjugated diolefin is emulsified with water and the resulting emulsion allowed to polymerize by maintaining at about 50-70°C. for several days. The proportion of water used in the emulsion need not be very great,<sup>106</sup> since successful polymerizations have resulted when the amount of water was insufficient to completely dissolve the emulsifying agents. A large variety of emulsifying agents have been suggested, but sodium oleate, sodium isobutyl-naphthalene sulphonate and egg albumin are most frequently employed.<sup>107</sup> The emulsion is maintained at a pH of 4.0-8.5 by buffering with sodium phosphate. The emulsion may be homogenized before polymerization.<sup>108</sup> Colloids

<sup>108</sup> H. Lecher and A. Koch, U. S. P. 1,789,873, Jan. 30, 1931, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1931, 25, 1412. German P. 526,304, 1928; *Chem. Abs.*, 1931, 25, 4443. British P. 304,923, 1928; *Chem.*

such as carrageen moss extract, gum arabic, and higher alcohols are used to facilitate emulsification.<sup>109</sup> Emulsions of butadiene hydrocarbons in water may be prepared also in the presence of the hydrochloride or acetate of certain high-molecular-weight bases, such as diethylaminoethyloleamide and 2-n-pentadecylglyoxalidine.<sup>110</sup> Polymerization is effected by maintaining the emulsion at 50-70°C. for several days.

Lecher and Koch<sup>111</sup> effectively polymerized a butadiene hydrocarbon by employing two emulsifying agents, one being soluble in water (sodium oleate) and the other soluble in the hydrocarbon (magnesium oleate). The reaction is completed after 5-6 days of heating at 60-70°C. However, the presence of oxygen or substances yielding oxygen has been found to speed up the process and to increase the yield. Perborates,<sup>112</sup> hydrogen peroxide,<sup>113</sup> benzoyl peroxide, manganese borate<sup>114</sup> and colloidal or finely divided metallic oxides such as manganese dioxide and lead dioxide, as well as the oxides of mercury, silver, nickel, cobalt and chromium have been used.<sup>115</sup> Emulsions of 1,3-dienes in water may be polymerized in the presence of hydrazine or its derivatives, e.g., hydrazoisobutyric acid, hydrazine dicarboxylic acid, ethyl ester or sodium phthalyl hydrazide.<sup>116</sup> Emulsified diolefins may, in addition, be polymerized in the presence of hexachloroethane, carbon tetrachloride, ethylene dichloride, chlorobenzene, sodium trichloroacetate, and similar chlorinated compounds.<sup>117</sup> Amyl ether<sup>118</sup> has also been used for this purpose. Benzene-soluble rubbery polymers are obtained by carrying out the polymerization in emulsion at 10-20°C. and arresting the polymerization when 20 to 30 per cent of the diolefin remains unpolymerized.<sup>119</sup> A rubber-like product<sup>120</sup> results when an aqueous emulsion of a vegetable oil, e.g., tung oil, is polymerized with butadiene or isoprene in the presence of oxygen or an oxidizing compound. Another emulsion-polymerization<sup>121</sup> carried out in the presence of oxidizing agents yields polymers free from difficulty soluble substances by including such additional compounds as phenols, hydroquinone, resorcinol, pyrocatechol, acetic acid and acetone. Iodine, colloidal sulphur and arsenious acid are also said to be useful for this purpose.

Where hydrogen peroxide or similar oxidizing agents are used to effect conversion, reducing materials, such as sodium bisulphite, sodium hydro-bisulphite, or

stannous chloride, are added to the polymerized latex to decompose excess oxidizing agent and to give paler products.<sup>122</sup> Emulsion polymerization is said to be facilitated by the presence of an unsaturated nitrile of acrylic acid or its methyl or butyl esters.<sup>123</sup> Polymerization of olefins of the butadiene type<sup>124</sup> has been effected, moreover, in the presence of compounds such as ethyl sorbate, ethyl cinnamate, 2-methyl-3-chlorobutadiene, 3-chlorostyrene and sorbic acid methyl ketone,  $\text{HOOC}-\text{CH}=\text{CH}-\text{CH}=\text{CH}-\text{CH}_2-\text{CO}-\text{CH}_3$ . By aqueous extraction of the cortex of rubber trees a non-rubber substance is obtained which is recommended as a catalyst for the emulsion-polymerization of diene hydrocarbons.<sup>125</sup> Rubber-like products of high elasticity and strength are obtained upon vulcanization in the presence of finely divided carbon.<sup>126</sup> A creamy or jelly-like product results<sup>127</sup> when butadiene hydrocarbons are stirred or shaken with aqueous solutions of the polymerization promoters.

The coagulation of the emulsified polymerization products may be accomplished by several methods. A common procedure consists in cooling the batch below 0°C.<sup>128</sup> The addition of salts of the alkali metals,<sup>129</sup> e.g., sodium chloride, sodium carbonate and sodium hydrogen phosphate is also quite effective. Such emulsions may be concentrated by standard methods in the presence of sodium oleate or other protective colloids.<sup>130</sup> The use of proteolytic enzymes<sup>131</sup> including papain, pancreas extract or banana juice has been recommended for this purpose. In every instance, the removal of unchanged diolefin before coagulation is advantageous.<sup>132</sup>

**"Sodium" Polymerization.** This polymerization is effected by agitating a mixture of the diolefin and an alkali metal or an alloy.<sup>133</sup> The polymerization may be carried out in successive stages by varying the temperature of reaction. For example, butadiene is treated with sodium amalgam at 0-6°C. for two days. The temperature is then raised to 30-40°C., sodium is added and the mixture allowed to stand for several days.<sup>134</sup> A catalyst of sodium particles of uniform size (balls of 1.1 mm. diameter) obtained by comminuting in a liquid and sieving, is said to be effective.<sup>135</sup> A convenient catalyst for polymerizing butadiene at 35-45°C. consists of sodium dispersed in a finely divided solid diluent, i.e., 1.5 parts of sodium ground

with 60 parts of dry sodium chloride.<sup>136</sup> Besides metallic sodium, various alloys and derivatives of that element have been particularly recommended as catalysts. Midgley, Hochwalt and Thomas<sup>137</sup> use an alloy of sodium and potassium which is liquid under the conditions of reaction, for polymerizing diolefins. Polymerization can be effected in the presence of sodium, potassium, calcium and their alloys or organic compounds of alkali or alkaline earth metals which are not capable of ionization, such as sodium ethyl, sodium triphenylmethyl and lithium alkyls. The catalyst is added in three or more fractions.<sup>138</sup> The polymerization is carried out in an atmosphere of nitrogen, carbon dioxide or other inert gas. Diluents which may facilitate the reaction include dioxane, vinyl ether, vinyl chloride and acetals. The use of hydrogen is said to be advantageous; increase in hydrogen pressure lowers the viscosity of the polymerized product.<sup>139</sup> Butadiene hydrocarbons may also be polymerized in the presence of sodium hydride<sup>140</sup> or of sodium with addition of small quantities of water during reaction.<sup>141</sup> The water is added in the form of water of crystallization of salts (e.g.,  $\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$  or  $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ ).

The polymerization reaction employing metallic sodium, or alkali metals generally, is accelerated or modified considerably by various organic materials. Thus the presence of hydrocarbon diluents such as butylene, cyclohexane, benzene, turpentine or gasoline is said to be advantageous. The greater the amount of diluent used, the greater is the proportion of polymerization product soluble in benzene and the lower is the viscosity of the solutions obtained.<sup>142</sup> Readily soluble rubber-like products are obtained by polymerizing in the presence of sodium, using solvents or dispersion media such as decahydronaphthalene, dry xylene, toluene, tetrahydronaphthalene, benzene, cyclohexane or liquid polymerization products of the process.<sup>143</sup> For example, Schmidt<sup>144</sup> prepared a thinly viscous product by polymerizing butadiene with sodium in the presence of cyclohexane. The material was recommended as a protective coating for wood and metal. Soluble plastic polymerization products are also obtained by continuously removing the soluble substances as formed, employing light petroleum, ether or benzene as solvent.<sup>145</sup>

Among the numerous substances which have been said to exercise a favorable influence on the polymerization of diolefins to rubber-like substances, in the presence of sodium or an alkali metal, the following may be mentioned:

- (1) Starch, cellulose, or cellulose ether.<sup>146</sup>
- (2) Ethyl or phenyl ether or an olefin oxide or peroxide.<sup>147</sup>
- (3) Ammonia or a free cyclic or aliphatic base to the extent of 0.01 to 1 per cent of the hydrocarbon polymerized.<sup>148</sup>

- (4) A cyclic diether such as dioxane.<sup>149</sup>
- (5) Twenty per cent of a low-boiling aliphatic ether such as dimethyl, diethyl, or methyl ethyl ether.<sup>150</sup>
- (6) Less than 5 per cent of saturated simple ethers such as diethyl, diamyl, or diisobutyl ether.<sup>151</sup>
- (7) Aldehydes, ketones or saturated and unsaturated acyclic or cyclic acetals, or acetals from 1,2- and 1,3-glycols.<sup>152</sup>
- (8) Up to 20 per cent of an organic compound unattacked by sodium but capable of replacing sodium by hydrogen in sodium triphenylmethyl, e.g., dioxane, furan, thiophene, acrylonitrile, phenylacetone. The presence of an unsaturated ether such as vinyl ethyl ether is also desirable.<sup>153</sup>
- (9) Up to 1 per cent of organic halogen compounds, such as ethylene dichloride, vinyl chloride, benzyl chloride, 1,2-dibromocyclohexane, 3-chloroquinoline or 1-chloronaphthalene.<sup>154</sup>

**Other Methods of Polymerization.** Anhydrous halides of the amphoteric elements, including the tetrahalides of tin and titanium, the tri- and pentahalides of antimony, boron chloride, halides of arsenic, iron and bismuth, as well as certain strongly negative substances such as sulphuryl chloride, phosphorus pentoxide, and phosphorus oxychloride have been suggested by Staudinger and Bruson<sup>155</sup> to polymerize diolefin hydrocarbons to give rubber-like products. Treatment of isoprene in benzene solution in the cold with stannic chloride yields a white rubber-like mass, soluble in benzene. This, together with the white powdery polymer of 1-phenylbutadiene, and the white rubbery polymer of cyclopentadiene can be vulcanized with sulphur chloride or they can be used in the preparation of lacquers.

A two-stage polymerization process, combining both the "sodium" and "emulsion" methods for preparing rubbery polymers, has been proposed.<sup>156</sup> For example, isoprene is partially polymerized with sodium at 35°C. Additional isoprene is incorporated and the mixture is emulsified with sodium oleate. The final polymerization is carried out at 60°C. Other stepwise processes have been used in which the method of polymerization does not change.<sup>157</sup>

Plauson<sup>158</sup> produced soluble rubber-like materials by polymerizing diolefins in mixture with drying oils in the presence of zinc chloride or aluminum chloride at ordinary or higher temperatures. Gerke<sup>159</sup> obtained synthetic rubber-polymers by treating a 1,3-diolefin with an inorganic peroxide (barium peroxide) and an organic acid anhydride (acetic anhydride). Butadiene may be polymerized by heating under increased pressure in the presence of oxygen and anhydrous organic solvents, e.g., tetrahydrostyrene, benzene or toluene. The resulting solution of

polymers may be used in the manufacture of adhesives or coating and binding compositions.<sup>100</sup>

Methods have been described whereby the synthesis of diolefins and their subsequent polymerization to rubber-like polymers may be carried out in one operation.<sup>101</sup> For example, ethylene and acetylene and an added inert gas are heated in an autoclave under a pressure of 55-60 atmospheres at 350-400°C. The 1,3-butadiene so formed polymerizes when the reaction is performed in the presence of an alkali metal. Highly plastic masses resembling rubber are formed by heat-polymerizing butadiene hydrocarbons in the presence of unsaturated ketones.<sup>102</sup>

The polymerization of diolefins is catalyzed by small amounts of the carbonyls of heavy metals, e.g., those of iron, nickel, cobalt, molybdenum, tungsten and chromium. Isoprene is converted into a rubber-like mass by warming with 2 per cent of iron carbonyl in a current of air. Nickel carbonyl or iron carbonyl added with chromium propylnaphthalenesulphonate to a paint of polymerized butadiene in toluene accelerates the hardening of the film.<sup>103</sup>

According to Bysov<sup>104</sup> the polymerization of diolefins to synthetic rubbers is favored by the presence of (1) the dimer of the diolefin, which suppresses further undesirable formation of oily polymers, and (2) mixtures of substances capable of existing in tautomeric forms, such as ethyl benzoylacetate with diazoaminobenzene or phenylthiocarbimide. Synthetic rubber-like materials have been prepared<sup>105</sup> by polymerization in successive stages. The polymerization is partially completed and then additional quantities of the same or a different hydrocarbon are added. For example, if butadiene or isoprene represents the initial material, a different compound such as 2,3-dimethylbutadiene may be added.

Bridgman and Conant<sup>106</sup> were successful in polymerizing to rubbery materials such unsaturated hydrocarbons as isoprene, 2,3-dimethyl-1,3-butadiene and styrene at pressures of 3000-12,000 atmospheres at room temperature. At 12,000 atmospheres, isoprene yielded a tough, transparent, rubber-like solid which was 100 per cent polymerized. The reaction time is much less than can be obtained by any other method of polymerization, being 50 hours in this instance. Styrene, when subjected to pressure, yielded a hard resin, but when mixed with an equal part of malonic ester and subjected to 12,000 atmospheres, a soft, white, rubbery mass resulted. Vinyl acetate was also completely polymerized to a transparent rubber-like solid at high pressures.

In order to separate a mixture of olefins into monolefins and diolefins, Brooks<sup>107</sup> treated the mixture with a dispersion of finely divided cuprous chloride in aqueous ammonium chloride. The cuprous chloride reacts with the diolefins but not with the monolefins so that the two are easily separated. The diolefins are regenerated by heating and can then be polymerized to a rubber-like material.

## VISCOUS OR OILY POLYMERS OF BUTADIENES

Reference has already been made to the oily by-products obtained during the polymerization of 1,3-diolefins to rubber-like materials. Highly viscous oils have been obtained by heating butadiene or its methyl derivative to 220°C. under pressure. However, if the temperature is not allowed to exceed 150°C. clear oils result. Polymers procured in this manner are recommended as constituents of paints, varnishes and adhesives.<sup>168</sup> Oily polymers are also prepared<sup>169</sup> by treating butadiene and its homologues at high temperatures and at ordinary pressures in the presence of nickel, aluminum, glass wool, silica gel, or spongy iron. It is said that in general butadiene and other olefins, obtained from the destructive distillation of coal, may be polymerized to yield products useful as lubricating oils and plastics.<sup>170</sup>

By heating a mixture of butadiene, benzene, ligroin and xylene at 180°C. and under 80 atmospheres for 4 hours, a polymerized product said to be of value in the preparation of transparent lacquers is formed.<sup>171</sup> Oils for varnishes are made by heating butadiene and similar hydrocarbons to 120-180°C. under pressure in the presence of oxygen or gases containing, or yielding, oxygen.<sup>172</sup> For coating and adhesive compositions the oily polymerization products of diolefins are used in admixture with cellulose derivatives or synthetic resins, along with various fillers.<sup>173</sup>

Resinous, non-rubber-like products result on heating diolefins with substantial quantities (e.g., 1 to 5 parts) of an inorganic acid, preferably of sulphur or phosphorus, or an organic derivative such as benzenesulphonic acid.<sup>174</sup> However, branched-chain olefins if polymerized at -10°C. in the presence of boron trifluoride, aluminum chloride or similar inorganic halides yield viscous, semi-solid products. The estimated molecular weights of these polymers range from 1000 to 10,000.<sup>175</sup>

Products of varying degrees of usefulness have been obtained<sup>176</sup> by separating the fractions resulting from the polymerization of butadiene hydrocarbons. Separation is effected by selective solvent action. For example, one fraction is recommended for use in the manufacture of artificial silk and another for coatings or impregnation of paper. Fractions are also obtained having the requisite properties necessary for vulcanization to synthetic rubber. Hard flexible foils, as exemplified in films, bands and lacquer coatings, possessing considerable resistance to chemical influences have been prepared by subjecting a non-distillable polymerization product of a diolefin to heat treatment in the presence of oxygen.<sup>177</sup> Similar materials are prepared by using sulphurizing agents instead of oxygen.<sup>178</sup>

## POLYMERIZATION OF CYCLIC 1,3-DIOLEFINS

Like the simple straight-chain conjugated diolefins, the cyclic diolefins, cyclopentadiene and 1,3-cyclohexadiene also possess a great tendency to polymerize to

high-molecular-weight resinous polymers. These products, however, differ somewhat from the rubber-like polymers of butadiene and isoprene.

**Cyclopentadiene.** By polymerization under controlled conditions, cyclopentadiene has been shown to yield a whole series of lower polymers, including the dimer, trimer, tetramer, and pentamer, as well as a complex polycyclopentadiene  $(C_5H_6)_x$ , where  $x$  may vary within the limits 20-100. The polymerization of cyclopentadiene<sup>179</sup> to solid polymers proceeds spontaneously on standing at ordinary temperature, particularly in the presence of air or oxygen, but is more rapid at higher temperatures.<sup>180</sup> Light has little influence on the reaction.<sup>181</sup> However when small amounts of ethyl mercaptan are added to the cyclopentadiene, resin-formation takes place upon standing in light.<sup>182</sup> By heating cyclopentadiene to 135°C., dicyclopentadiene<sup>183</sup> is formed mainly, but by prolonging the heat treatment and employing higher temperatures other polymers can be obtained.<sup>184</sup> These polymers are crystalline solids (up to the pentamer, at least) and can be separated from one another by vacuum distillation. Each polymer contains two double bonds and can be hydrogenated to the corresponding dihydro- and tetrahydro derivatives. By thermal treatment they can be partially depolymerized with the formation of cyclopentadiene and its lower polymers. The melting points of the lower polymers of cyclopentadiene are given in Table 23.

TABLE 23.—Polymers of Cyclopentadiene.

Compound	Melting Point °C.
Dicyclopentadiene . . . .	{ 32.5 (α-form) 19.5 (β-form)
Tricyclopentadiene . . . .	60
Tetracyclopentadiene . . . .	188-190
Pentacyclopentadiene . . . .	270
Polycyclopentadiene . . . .	decomposes above 300

The chemical constitution of these crystalline polymers has not been definitely decided. Wieland<sup>185</sup> proposed a formula which assumes the addition of a cyclopentadiene molecule activated in the 1,4 position to another molecule at the 1,2 position. The investigations of Alder and Stein<sup>186</sup> tend to corroborate this formula which may be represented by the graphic structure

<sup>179</sup> In the case of the spontaneous polymerization of cyclopentadiene to its dimer the reaction is practically independent of the presence of oxygen. See G. R. Schultze, *JACS*, 1934, 56, 1552.

<sup>185</sup> H. Wieland, *Ber.*, 1906, 39, 1492.

<sup>186</sup> K. Alder, G. Stein, and others, *Ann.*, 1932, 496, 204; 1933, 504, 216; *Brit. Chem. Abs.*, 1932, 988; *Chem. Abs.*, 1933, 27, 5811. *Ber.*, 1934, 67, 813; *Chem. Abs.*, 1934, 28, 6114. *Angew. Chem.*, 1934, 47, 837; *Chem. Abs.*, 1935, 29, 2516.

Furthermore, the latter investigators assert that the lower polymers of cyclopentadiene form an homologous series of the general formula

in which  $x$  is a small integer.

Additional corroboration for the Wieland formula has been made available through the researches of Pirsch<sup>187</sup> on the molecular depression of the melting point. The argument is based on observations that dicyclic compounds, whose molecular structure is almost equally developed in all three spatial directions, have very high values for molecular melting point depressions.<sup>188</sup> The results obtained with  $\alpha$ -dicyclopentadiene were in accord with this view.

An alternative formula for the structure of dicyclopentadiene was originally advanced by Kraemer and Spilker.<sup>189</sup> If 1,2 addition takes place the dimer may be represented by the graphic formula

This formula is supported by Staudinger and Rheiner<sup>190</sup> who assign to the non-resinous polymers of cyclopentadiene the constitution

where  $x$  is a relatively small integer.

**Polycyclopentadiene.** Products very different from the simple crystalline polymers described in the preceding section are obtained when cyclopentadiene is subjected to the action of various strong polymerizing agents, the best being stannic chloride and antimony pentachloride. Boron trichloride, titanium tetrachloride, arsenic halides, ferric and bismuth halides, sulphuryl chloride, phosphorus pentoxide

<sup>187</sup> J. Pirsch, *Ber.*, 1934, 67, 101; *Brit. Chem. Abs.*, A, 1934, 285.

<sup>188</sup> K. Alder and G. Stein (*Ber.*, 1934, 67, 373; *Chem. Abs.*, 1934, 28, 3061) are of the opinion that molecular melting point depressions are of limited value in the determination of configuration in the case of cyclopentadiene polymers. It is pointed out that both configurations, under question, are capable of existing in stereoisomeric forms; hence either of the proposed formulas is capable of fulfilling the conditions for high molecular melting point depressions.

<sup>189</sup> G. Kraemer and A. Spilker, *Ber.*, 1896, 29, 552; *J.C.S.*, 1896, 70 (1), 289.

<sup>190</sup> H. Staudinger and A. Rheiner, *loc. cit.*

and phosphorus pentachloride exert a somewhat less vigorous polymerizing action. With stannic chloride the reaction is so vigorous that strong cooling in conjunction with an inert liquid diluent must be employed. The product in every case is a white amorphous powder somewhat resembling rubber. However the resin obtained by polymerizing dicyclopentadiene with heat and pressure is quite hard and resembles amber.<sup>101</sup> The rubber-like polymers are insoluble in acetone, ether and alcohol, although colloidal solutions are formed with common rubber solvents. When dried at 50°C. in a high vacuum the polymer swells to a spongy brittle white mass which can be powdered. Polymerized cyclopentadiene has an empirical composition corresponding to  $(C_5H_6)_x$  and a molecular weight which varies between about 1260 and 6670. The pure compound is unsaturated and contains one double bond per  $C_5H_6$  unit. It appears that polycyclopentadiene, or "cyclopentadiene rubber," consists of a series of hydrocarbons of the general formula:<sup>102</sup>

in which x is an integer varying from about 20 to 100.

When exposed to air, cyclopentadiene rubber gradually takes up oxygen to the extent of about 19.5 per cent by weight to give a deep-orange powder of the composition  $(C_5H_6O)_x$ . Polycyclopentadiene can also be vulcanized with sulphur chloride in chloroform solution to yield products varying from a soft gel to a hard-rubber ebonite material, which can be pulverized only with great difficulty. All these vulcanized products are insoluble in organic solvents.

Polycyclopentadiene is attacked by ozone, nitrogen trioxide, and hydrogen chloride, and can be hydrogenated to a brown, glassy, insoluble mass. According to Bruson and Staudinger,<sup>100</sup> polycyclopentadiene might find application as a lacquer base rather than as a rubber substitute.

Gum-like modifications of polycyclopentadiene have been found in appreciable quantities in mains for the distribution of coke-oven gas and carburetted water-gas. The formation of such gummy and resinous polymers presents a serious problem with regard to clogging of meters and small pipes. Shively suggested<sup>104</sup> that the polymerization of dienes in the pipe-lines was promoted by the presence of traces of oxygen and favored by high pressures and humidities. An explanation for the effect of oxygen and pressure is afforded by the alternative view<sup>103</sup> that resinification takes place as a result of the vapor-phase condensation of the unsaturated hydrocarbon with nitrogen peroxide and the subsequent polymerization of the condensation products. The nitrogen peroxide is formed by the oxidation of nitric oxide which is unavoidably introduced into the gas during its manufacture. (See Chapter 35.)

**1,3-Cyclohexadiene.** This hydrocarbon is more resistant to polymerization than butadiene or its 2- and 3-alkyl derivatives and is more related, in this respect, to the 1- and 4-substituted butadienes. It is not acted upon by sodium. Con-

concentrated sulphuric acid reacts explosively with it to yield resins or tars.<sup>196</sup> Anhydrous metallic halides such as ferric chloride and aluminum chloride<sup>197</sup> convert it into resins. On heating at 200-220°C. for several hours, the hydrocarbon is largely polymerized with the production of a solid rubber-like polymer ("dihydrobenzene rubber") and a terpenic dimer. Practically no polymerization occurs on heating cyclohexadiene below about 120°C. The dimer of cyclohexadiene is a liquid which is resinified by concentrated sulphuric and nitric acids. Hofmann and Damm<sup>198</sup> have assigned the following formula to dicyclohexadiene:

This structure has been confirmed by Alder and Stein.<sup>199</sup>

Useful resins are said to be obtained by treatment of cyclohexadiene with polymerizing agents in the presence of diluents.<sup>200</sup> Thus, 200 parts of cyclohexadiene, 500 parts of glacial acetic acid and 5 parts of 97 per cent sulphuric acid are boiled for 7 hours, the acetic acid removed by vacuum distillation and the sulphuric acid by washing with water and mild alkali. The product is a clear, glassy solid which is soluble in turpentine or benzene. Aluminum chloride has also been suggested as a polymerizing agent. For instance, 6 parts of anhydrous aluminum chloride are slowly added, with cooling, to 30 parts of cyclohexadiene, and the mixture is heated at 40°C. until reaction ceases. The mass is extracted with benzene, the extract washed with soda solution and the benzene distilled off to yield a colorless resin. Alternatively, the reaction mixture is washed with dilute hydrochloric acid and the resin distilled with steam. In a similar way, resins may be prepared from 1-methyl-1,3-cyclohexadiene.

A thick, amber-yellow resinous substance was obtained by Zelinsky and Titova<sup>201</sup> by allowing 1,3-cyclohexadiene to absorb oxygen to the limit of its capacity. The analysis indicated that the product contained 1 mol of oxygen per mol of cyclohexadiene and in view of its resinous nature, a dimeric formula,  $C_{12}H_{16}O$ , has been suggested.

#### Co-POLYMERIZATION OF DIOLEFINS

Synthetic resins are now being prepared by the condensation of diolefins with olefins in cracked-gasoline fractions under the influence of aluminum chloride. Several reactions occur in this treatment, including polymerization of the diolefin, condensation of the diolefin with a monoolefin, and condensation of diolefins with

<sup>196</sup> A. Baeyer, *Ber.*, 1892, 25, 1841.

<sup>197</sup> N. D. Zelinsky, Y. I. Denisenko, M. S. Eventova and S. I. Khromov (*Sintet. Kauchuk*, 1933, 4, 11; *Chem. Abs.*, 1934, 28, 3617) found that 1,3-cyclohexadiene polymerized when heated with aluminum chloride and that 1,4-cyclohexadiene was partially polymerized and partially dehydrogenated to benzene.

aromatic hydrocarbons. The two latter reactions both give rise to hard resins under appropriate conditions.

**Condensation of Diolefins with Monolefins.** When anhydrous aluminum chloride is placed in pure isoprene, no temperature rise occurs and there is no appreciable reaction, though a small amount of insoluble polymer is formed on long standing. If, however, a small amount of a monoolefin hydrocarbon, such as 2-pentene or trimethylene, is introduced into this mixture a vigorous reaction takes place immediately. Certain phases of this interesting reaction were investigated and discussed by Aschan.<sup>202</sup> Later, Thomas and Carmody<sup>203</sup> investigated the products of the reaction between 2-pentene and isoprene in the presence of aluminum chloride at 1-4°C. After decomposition of the reaction mixture with water, two types of product were obtained, namely, an insoluble polymer approximating in composition to  $(C_6H_8)_x$ , and a soluble polymer, ranging from a viscous

FIG. 48.  
Relationship Between Two Polymers as 2-Pentene is Added to Isoprene. (C. A. Thomas and W. H. Carmody)

Courtesy Industrial and Engineering Chemistry

oil to a hard resin. The relative proportions of these two products and also the hardness of the soluble polymer depended upon the proportions of 2-pentene and isoprene employed. The amount of soluble polymer increased and its hardness diminished with increasing proportions of 2-pentene. Only small amounts of soluble polymer (and large amounts of insoluble polymer) were formed with small proportions of 2-pentene. (See Fig. 48.) Subsequent experiments have indicated that 2-pentene produces this effect by acting as a mutual solvent for the isoprene and the aluminum chloride.<sup>204</sup>

The soluble polymer, which is of technical interest, consists of a mixture of higher oils and a hydrocarbon resin, the hardness depending upon the amount of oils present. The resin is soluble in most hydrocarbon solvents and drying oils. On exposure in thin films to air, the resin slowly oxidizes, becoming harder. The insoluble polymer, on the other hand, is a white granular material, which tends to depolymerize at 116°C. This material is probably a true polymer of isoprene.

The application of these observations to the manufacture of a synthetic resin, which may find use in the paint and varnish industries, has been described by Thomas and Carmody.<sup>205</sup> A cracked-gasoline distillate containing diolefins, mono-

FIG. 49.—Effect of Catalyst on Density and Yield of Resin from Cracked Gasoline. (C. A. Thomas and W. H. Carmody.)

rate of addition may be somewhat increased. After a time a point is reached when no more heat is evolved. The distillate darkens in color as polymerization proceeds and the specific gravity increases 10 to 15 per cent. With increasing proportions of catalyst, the yield of resin rises to a maximum and its iodine value falls to a minimum. (See Figs. 49 and 50.) The effectiveness of the catalyst is believed to be proportional to the amount of it that goes into solution. About 6 hours is required for complete polymerization. After the completion of the polymerization the reaction mixture is treated with an alkali and the precipitated aluminum hydroxide and insoluble polymer are filtered off. The filtrate, consisting of a solution of the soluble resin, is first distilled under reduced pressure and then steam is passed directly into the molten resin. A diagram of the process for obtaining resins from petroleum distillates is given in Fig. 51. By controlling the time and temperature of the steam treatment, the hard-

<sup>206</sup> See B. V. Buizov (*J. Applied Chem.*, U. S. R., 1933, 6, 1074; *Chem. Abs.*, 1934, 28, 5711) for another description of rubber-preparation from petroleum.

ness of the resin can be varied within certain limits. The resulting resin may be used for various industrial purposes. For varnish making, a light-amber-colored, hard, brittle material, melting at 110-115.6°C. (ball and ring method), may be prepared. This resin is soluble in practically all hydrocarbon solvents, and all acetic acid esters except ethyl acetate. It also dissolves readily in drying oils, such as linseed oil and tung oil. With the latter drying oil the resin makes varnishes which dry quite rapidly.<sup>307</sup> The resin is insoluble in methanol, ethyl alcohol, ethyl acetate, and acetone. It is practically neutral and its iodine value can be varied to bring out unusual characteristics. For example, on baking a film, prepared from a highly unsaturated resin in petroleum solvents, at 105°C. for one hour, the film becomes insoluble in its original solvents. This phenomenon is comparable with the drying of unsaturated oils.

Later investigations<sup>308</sup> on preparation of resins from petroleum revealed that the nature of the final product can be varied by employing different proportions of two cracked-distillate fractions, one boiling at 25-50° and the other at 125-180°. It was also found that the insoluble polymer referred to above can be converted into a use-

ful resin. The filter residue is freed of inorganic matter (e.g., aluminum chloride) by repeated washings with hydrochloric acid (10 per cent). After this treatment there remains a white granular material insoluble in most solvents. By heating this mass at 300° out of contact with air a light amber-colored resin results which is soluble in drying oils and in benzene, gasoline and naphtha.

According to Schering,<sup>309</sup> oils and resins are formed by condensing diolefins (butadiene, isoprene, or dipentene) with monoolefin hydrocarbons (amylene, diamylene, menthene, pinene, camphene and styrene) in the presence of catalysts, e.g., anhydrous aluminum chloride, ferric chloride, boron trichloride, and magnesium chloride. Sodium stearate<sup>310</sup> has also been recommended as a catalyst for use in the polymerization of mixtures of butadiene hydrocarbons with monoolefin benzenes. Resinous materials were produced in this way by condensing butadiene and styrene. The products consist of an ether-soluble portion, a sticky solid, and an ether-insoluble yellow powder. Treatment of equal parts of camphene and isoprene with 5 per cent of aluminum chloride yielded an ether-soluble, soft solid and an insoluble residue, which was white or light yellow, easily pulverized and insoluble in most of the common solvents.

By condensation of a diolefin with styrene, rubber-like or plastic masses are obtained depending upon the proportions of the reactants. The polymerization

is carried out, after emulsification with sodium stearate or sodium mono- or dibutynaphthalenesulphonate, at 40-60°C. for several days.<sup>211</sup> The rubber-like products may be vulcanized<sup>212</sup> and used in the manufacture of conveyor belts, tires, driving-belts and coatings. Instead of styrene, other olefin benzenes such as polyvinylbenzenes or nuclear or side-chain homologues of styrene may be used. For example, butadiene and  $\alpha$ -methylstyrene are polymerized in aqueous emulsion in the presence of diethylaminoethyloleamide at 60°C. for 4 to 5 days to yield a synthetic rubber.<sup>213</sup> A mixture of a diolefin and vinyl-naphthalene (not more than 50 per cent) may also be polymerized in a similar way to furnish a latex which is coagulated and may be vulcanized with the addition of fillers, e.g., lampblack.<sup>214</sup>

A material resembling rubber or deresinated gutta-percha, and capable of replacing rubber in the insulation of submarine cables, is prepared by polymerizing

FIG. 51.—Schematic Representation of the Production of Resins by Treatment of Cracked Petroleum Distillates with Aluminum Chloride. (C. A. Thomas and W. H. Carmody.)

a mixture of a butadiene hydrocarbon and an aromatic olefin (styrene, naphthyl-ethylene, and divinylbenzene) at 20-200°C. in the presence of a catalyst, such as sodium or sodium amalgam, and, if necessary, of an antioxidant and a hydrocarbon swelling agent to render the product thermoplastic.<sup>215</sup> Similarly, polyolefinic benzene derivatives (e.g., styrene, divinylbenzene) may be mixed with a double proportion of butadiene and polymerized. However, in this case the reaction is carried out in any aqueous emulsion.<sup>216</sup>

**Condensation of Diolefins and Monoolefins with Aromatic Compounds.** Thomas and Carmody<sup>217</sup> have found that isoprene condenses with a number of benzene homologues in the presence of anhydrous aluminum chloride, yielding hard resins. Benzene homologues employed in the condensations included toluene, o-, m- and p-xylene, ethylbenzene, propylbenzene, isopropylbenzene, hexamethyl-

benzene, sec-butylbenzene, tert-butylbenzene and tert-amylbenzene. No appreciable amount of resin was obtainable in the condensation of isoprene with benzene. However, Thomas<sup>218</sup> prepared a resin by polymerizing a solution of impure dipentene in benzene using aluminum chloride as a catalyst. Hexadienes, butadienes and dimethylbutadiene as well as isoprene are suggested for resin manufacture with homologues of benzene and aluminum chloride. Other resins have been prepared by the reactions of various mixtures of olefins and diolefins with substituted benzenes.<sup>219</sup> Among these are the reaction of a substituted benzene with (A) a cyclic diolefin and an open-chain monolefin; (B) a cyclic olefin and a straight-chain diolefin and (C) a cyclic olefin and a cyclic diolefin. Aluminum chloride is employed as catalyst.

Michel<sup>220</sup> was able to alkylate naphthalene and its hydrogenated derivatives with ethylene or other olefins using ferric chloride or aluminum chloride as catalysts. Only products recommended as motor fuels or dye intermediates resulted when the reaction was carried out at pressures of 20-30 atmospheres and at temperatures up to 200°C. Upon subjecting anthracene, phenanthrene or acenaphthene to analogous treatment using slightly greater pressures, resins and lubricating oils were produced.<sup>221</sup>

The reaction of 14 parts of isoprene and 50 parts of toluene at 160°C. under 2-7 atmospheres pressure (sodium catalyst) yields 3-methyl-5-phenylpentene as an oily liquid (b.p., 218-222°) with an aromatic odor.<sup>222</sup> Similar condensations have been effected between butadiene and tetrahydronaphthalene, 2,3-dimethylbutadiene and toluene and between butadiene and toluene. Rubber-like masses are obtained in small amounts in these reactions.

Berry and Reid<sup>223</sup> obtained ethyl derivatives with ethylene, and propyl derivatives with propylene, when benzene, toluene, bromobenzene, and cyclohexane were treated with these olefins in the presence of aluminum chloride. Tarry high-boiling products were formed at the same time in varying amounts.

Condensation products of 1,3-butadiene and cyclic hydrocarbons having at least one aromatic nucleus and no olefinic sidechains, or alkyl, halogeno, nitro, alkoxy, or carbalkoxy derivatives, can be prepared,<sup>224</sup> employing a catalyst such as aluminum chloride. Thus 1,3-butadiene is passed into mixtures of aluminum chloride and tetrahydronaphthalene, benzene, m-xylene, chlorobenzene and nitrobenzene. The products are stated to be useful as thermohardening bases for lacquers. Besides aluminum chloride, boron fluoride, or anisolv-acids<sup>225</sup> derived from these halides, may be used as catalysts. Soft resins are prepared by heating car-

<sup>225</sup> In extension of Werner's so-called "anhydro-acids," neutral molecules which combine with a solvent increasing its acidity by forming complex anions are called "anisolv acids." For example, when more than 1 mol of zinc chloride is present in a complex acid, the anion is regarded as the co-ordination center. Many other compounds such as magnesium chloride, zinc chlorate, sulphur dioxide, boron trioxide and pyroboric acetate increase the ionization of organic acids. Boron trifluoride is the most strongly acting anisolv-acid. Boron trifluoride-acetic acid boiling at 60°C. under 13 mm. pressure is as strong as sulphuric acid. H. Merwein, *Ann.*, 1927, 455, 227; *Brit. Chem. Abs.*, 1927, 886.

bazole with olefins at 100-200°C. in the presence of aluminum chloride, fuller's earth, tonsil, or franconite. For optimum results, the use of an inert solvent is said to be desirable.<sup>226</sup> The residue resulting from the refining of oils with liquid sulphur dioxide has been treated with olefins in the presence of aluminum chloride to produce a yellow oil and a resinous product.<sup>227</sup>

### VULCANIZATION OF RUBBER-LIKE POLYMERS

Vulcanizing procedures involving the use of sulphur alone have not, as yet, been successful in converting the polymerization products of butadiene and its homologues into finished synthetic rubber of good strength and elasticity. However, the incorporation of finely divided substances such as carbon, colloidal silicic acid or oxides of metals with the polymerization product materially increases the quality of the resulting vulcanized material.<sup>228</sup> Tschunkur and Bock<sup>229</sup> were successful in obtaining a synthetic rubber of good tensile strength and extensibility by vulcanizing stocks containing 30-80 per cent of their weight in carbon black. The tensile strength is reported as 150-275 kg. per sq. cm. with an ultimate elongation of 400 to 800 per cent. The tensile product (kg./sq. cm.  $\times$  % stretch) ranged from 50,000 to 190,000. On the other hand, vulcanization in the absence of carbon black gave products having a tensile product of only 15,000 to 40,000. The same workers have reported<sup>230</sup> that a synthetic rubber of good quality resulted when a mixture containing 45 per cent of polymerized styrene and 55 per cent of butadiene polymerizate was vulcanized with finely divided carbon comprising 20-70 per cent of the weight of the mixture. Polymerization products of vinyl-naphthalene have been suggested for use in an analogous manner with butadiene polymers. Products with a tensile strength of 30 to 50 kg. per sq. cm. and an ultimate elongation of 300 to 500 per cent have been obtained<sup>231</sup> by vulcanizing a polymerization product of butadiene and isoprene with 15 parts of zinc oxide, 3 parts of sulphur, 2 parts tar and 1 part diphenylguanidine. However, when the vulcanization was carried out with the addition of 50 parts of carbon black, the tensile strength ranged from 180 to 220 kg. per sq. cm. and the ultimate elongation had increased to 600-800 per cent. Similarly, a polymerization mixture prepared from a 10:3 mixture of butadiene and  $\alpha$ -methylstyrene<sup>232</sup> was compounded with 50 parts carbon black, 15 parts zinc oxide, 2 parts stearic acid, 1 part sulphur, 1.77 parts of an accelerator and vulcanized. The product had a tensile strength of 211 kg. per sq. cm., and an ultimate elongation of 500 per cent.<sup>233</sup>

The character of the finely divided carbon used modifies the properties of the vulcanized product. It is reported<sup>234</sup> that lampblack produces a more plastic and softer sodium-butadiene rubber with a much lower tensile strength than does carbon-black under the same conditions. It was found that rubber in-

<sup>232</sup> British P. 339,255, 1929, to I. G. Farbenind. A.-G.; *Brit. Chem. Abs.*, B, 1931, 264.

<sup>233</sup> It is reported that a mixture possessing practically the same tensile strength as ordinary synthetic rubber is obtained by using 25 per cent of reclaimed synthetic rubber in the mix and adding pine tar as a softener. See I. Belen'kii, *J. Rubber Ind.* (U. S. S. R.), 1934, 11, 345; *Chem. Abs.*, 1935, 29, 638.

<sup>234</sup> I. Raiz, G. Builo and A. Ermolaev, *J. Rubber Ind.* (U. S. S. R.), 1932, 8, 147; *Chem. Abs.*, 1933, 27, 2337.

creased in hardness very rapidly when the percentage of carbon black was increased above 45 per cent. Since the plasticity of sodium-butadiene rubber renders the ordinary milling operations impossible, methods for reducing such a characteristic are desirable in this instance. Farberov and Merzlikin<sup>286</sup> have reported that beneficial results were observed upon treating the crude synthetic rubber with dry steam in a vulcanizer and subsequently drying the material in a vacuum. A mixture of the resulting product with carbon black showed a decrease in plasticity of 20 per cent, calendered without difficulty and exhibited a 5-10 per cent increase in its resistance to tearing. Bock and Tschunkur<sup>286</sup> have reported that polymerized isoprene or similar hydrocarbons vulcanized in the presence of finely divided carbon black yielded products having an index of strength between 40,000 and 150,000.

Chesnokov<sup>287</sup> found that sodium-butadiene rubber when washed free of metallic sodium vulcanized best.<sup>288</sup> The addition of a naphthenic acid to neutralize the metallic sodium was not advantageous since an additional amount of sulphur was required (about 5.5 per cent more) and, in general, the vulcanization process was retarded. Vulcanization accelerators<sup>288</sup> such as aldehyde ammonia, previously dissolved in a solvent, favor the production of articles having improved elasticity and strength. Water, hydrocarbons, ethers, weak acids and liquid bases may serve as solvents for the accelerators. The addition of a bleached lignite wax to the material to be vulcanized facilitates mechanical treatment such as mixing and kneading.<sup>290</sup> Preservatives, including the hydroxy derivatives of biphenyl<sup>241</sup> and its substitution products and emulsified aldo- $\alpha$ -naphthylamine,<sup>242</sup> are said to be effective in preventing aging. The customary mastication process which precedes vulcanization may be avoided by incorporating the sulphur, fillers and particularly the carbon black while the polymerizate is still in the form of an emulsion.<sup>244</sup> Ermolaev and Bobrova<sup>244</sup> have investigated the effect of various inorganic substances on the properties of finished synthetic rubber products. They found that magnesium oxide was a good reinforcing agent, magnesium carbonate and kaolin produced soft materials indicating a medium reinforcing power, lithopone and zinc oxide have very little reinforcing action, chalk is not effective in this capacity, and barytes and lime can be used only when the product is not required to have elasticity. On the other hand, talc and infusorial earth gave products of excellent elasticity and lightness. Furthermore, Bock and Tschunkur<sup>245</sup> have asserted that such finely divided inorganic compounds can be substituted for lampblack to yield an acceptable synthetic rubber.

## APPLICATIONS OF POLYMERIZATION PRODUCTS

Interesting possibilities for the industrial utilization of the various polymerization products of olefins and diolefins have been advanced, and suggested applications have been extended to include such fields as the manufacture of automobile tires, electrical insulation, coating compositions, plastics and molded articles, adhesives, and synthetic fibers. The characteristics and uses of synthetic products obtained from chloroprene are dealt with in Chapter 8.

For the manufacture of automobile tires the polymerizates may be used alone or mixed with natural rubber, but in either case the crude material is vulcanized in the presence of lampblack.<sup>246</sup> A method for producing synthetic rubber of a mixed type is described by Tschunkur and Bock.<sup>247</sup> A butadiene polymerization product is mixed with at least 10 per cent by weight of natural rubber, 20-70 per cent of finely divided carbon black based on the weight of the mixture and a vulcanizing agent such as sulphur. Products, as prepared, have a tensile strength of 180 to 250 kg. per sq. cm. at a stretch of 500 to 800 per cent. In general the elasticity of synthetic rubber leaves much to be desired, hence it has been suggested that the treads be made from synthetic rubber and the side walls from natural rubber.<sup>248</sup>

The selection of polymerization products to be used in tire manufacture may be made on the basis of their relative viscosities in solutions of the same concentration.<sup>249</sup> Good resistance to the attrition and wear encountered by the tire treads may be obtained with a polymerizate of high viscosity.<sup>250</sup> For the side walls, however, a material of low viscosity is desirable. A composition for tires is also prepared by mixing butadiene polymerization products with natural or synthetic resins.<sup>251</sup> A mixture recommended for rubber soles for footwear consists of synthetic rubber (25), lampblack (20-30), kaolin (14.5-15), scrap rubber (22-30), sulphur (1.8), zinc oxide (1.5) and calcium oxide (2-3 per cent) and various accelerators and anti-agers.<sup>252</sup>

Since elasticity is not of prime importance in the manufacture of electrical insulating materials, synthetic rubber is readily adaptable to this purpose.<sup>253</sup> Schmidt<sup>254</sup> and his co-workers have prepared insulating products by heating non-distillable polymers of butadiene at 100-500°C. in the presence of a sulphurizing agent until the tensile elasticity is destroyed and the product sufficiently hardened. Insulation for submarine cables has been described<sup>255</sup> comprising 35-40 per cent of deresin-

ized gutta-percha or balata, 35-45 per cent of synthetic rubber and 10-30 per cent of hydrogenated synthetic or natural dealbuminized rubber. Submarine cables, designed to prevent incorporated magnetic material from being subjected to strains due to pressure and bending,<sup>254</sup> are filled with a polymerized cyclic terpene hydrocarbon as a pressure-equalizing compound. Rubber, gutta-percha or balata may be used along with the polymer. Cables may be coated also with a polymerization product of butadiene to which has been added magnesium oxide, lampblack and sulphur along with accelerators and anti-aging substances. The insulation is vulcanized at 100-150°C.<sup>257</sup>

Rubber dielectric compositions have been prepared in which a synthetic hydrocarbon polymerization product, e.g., polymerized styrene or butadiene, may comprise as much as 80 per cent of the composition, the remaining 20 per cent being rubber, gutta-percha or balata or a mixture of these.<sup>255</sup> A somewhat novel procedure involves the mibbing of the styrene by the rubber after which the styrene is polymerized by heating at 100° for 7-14 days. The composition is obtained in its finished form by masticating the polymerization mixture with wax.

Since synthetic rubber-like products may be obtained in a plastic condition, they may be molded or shaped and vulcanized until quite hard, thus yielding useful articles of many kinds. For example, Tschunkur and Bock<sup>256</sup> describe frost-resisting vessels which do not harden or become brittle at low temperatures. The plastic material comprises a mixture of polymerized isoprene and dimethylbutadiene mixed with sulphur, zinc oxide, tar, stearic acid, lampblack and diphenylguanidine. Hard masses for the manufacture of molded articles<sup>260</sup> are obtained by heating, without sulphur, the non-distillable polymers of butadiene or its derivatives to 100-500°C. However, before heating there may be added other polymerization products, solvents, rubber, fillers, coloring matter and plasticizers. The resulting resin may be similar to ebonite with good electrical insulating properties or it may be soft and pliable, depending upon the conditions of the reaction and added materials. Other similar hardened products have also been described.<sup>261</sup> A hard rubber-like composition said to be resistant to heat and chemical reagents has been prepared by Zieser<sup>262</sup> who polymerized mixtures of butadiene, natural rubber and sulphur using an alkali metal as the catalyst. The proportions of rubber used varied between 40 and 80 per cent and the proportion of sulphur added was large.

Synthetic rubber, such as may be obtained from isoprene, butadiene or dimethylbutadiene, is used in conjunction with other natural or synthetic plastic substances in the manufacture of products resembling leather, linoleum, ebonite, celluloid and artificial wood.<sup>263</sup> For example, a linoleum substitute contains 8 parts of dimethylbutadiene rubber, 5 parts of rosin, 5 parts of a mineral oil, 50 parts of cork, sawdust, peat meal, cellulose acetate or the like, 10 parts of heavy spar or lithopone, 12 parts of magnesia and 10 parts of ochre. After thorough mixing, the plastic

mass is rolled into sheets. A similar preparation<sup>264</sup> contains along with the usual fillers, methyl rubber W, nitrocellulose or linoxyn.

Coating compositions of various kinds have been described in which synthetic rubber products are the essential ingredients. Synthetic rubber in colloidal dispersions has been suggested as a base for the preparation of varnishes and lacquers.<sup>265</sup> A varnish-like material for coating the textile covering of airplane wings<sup>266</sup> contains polymerized butadiene hydrocarbons. Quick-drying coating materials<sup>267</sup> said to be transparent to light in a layer 2 inches in thickness are prepared by fractionating vapor-phase-cracked gasoline and polymerizing a fraction with a maximum boiling point of 112°C. Lacquer coatings<sup>268</sup> have been prepared from polymerization products hardened by air or oxygen in the presence of catalysts or by treatment with aluminum chloride, sulphur or sulphur dichloride. Complex products said to be useful as lacquer components may be derived from the polymerization of mixtures of butadiene and stand oil (linseed oil previously heated to 315°C. without driers).<sup>269</sup> Squalene, a hydrocarbon of the formula  $C_{40}H_{70}$  containing 6 conjugated double bonds and 8 methyl groups, was found to be of little value in paint making, since films of its polymerization product were quite brittle, swelled in water and were completely destroyed by sodium hydroxide.<sup>270</sup>

A road-making composition recommended by Bond<sup>271</sup> is prepared by stabilizing an aqueous dispersion of synthetic rubber through the addition of at least 150 per cent by weight of portland cement. Vulcanizing agents and compounding ingredients may also be included to suit the particular conditions under which the material is to be used. It is also said that the addition of 1-20 per cent of diolefin polymerizates produces a beneficial effect upon the elasticity and stability of road-construction materials when subjected to cold weather.<sup>272</sup> Brown<sup>273</sup> advocates employing synthetic rubber as a coating for a plastic, bituminous flooring material.

A somewhat unusual application of polymerization products has been proposed in the preparation of a substitute for reinforced glass.<sup>274</sup> The method of manufacture involves the application of a soft coating of a polymerization product of butadiene to an open-meshed fabric such as a mesh of tinned iron wire or vegetable fiber and hardening the film with oxygen or heat. A hard, transparent product results. Hydrogenated butadiene polymers are said to be applicable as an intermediate layer between two glass sheets in the manufacture of non-splintering glass.<sup>275</sup>

The polymerization products of butadiene and other diolefins along with their condensation and transformation products have been found adaptable to the manufacture of synthetic fibers, foils and the like. A characteristic process for the preparation of foils and threads<sup>276</sup> consists in coating glass plates with synthetic rubber (from butadiene) dissolved in cyclohexane or methylene dichloride. After

Schmidt, German P. 568,906, 1928; *Chem. Abs.*, 1933, 27, 2845. German P. 533,145, 1933; *Chem. Abs.*, 1934, 28, 1222. German P. 377,732, 1933; *Chem. Abs.*, 1934, 28, 685.

the solvent has evaporated the product is treated with sulphur chloride vapor to form a thin transparent foil. Threads are made in a similar manner except that the rubber solution is forced through an orifice to form the filament. A crimped or curled effect can be imparted to the fiber<sup>277</sup> by immersion in organic swelling agents such as solutions or emulsions of dipentene, cyclohexane, ethers, esters, and ketones. For example, a fiber with a wool-like appearance results by allowing dipentene to exert its action upon the threads for 100 minutes at 45°C.

Wulff, Moll and Breuers<sup>278</sup> state that the addition of about 0.5 per cent of hydrocarbons such as polymerized styrene, indene and hydrogenated natural or synthetic rubber greatly improves the viscosity, pour point and stability of lubricating oils. Alternatively the unpolymerized hydrocarbons may be added and subsequently polymerized *in situ*.

Other uses for diene polymerization products include the utilization of their benzene solutions as adhesives.<sup>279</sup> Thus, solutions of mixtures resulting from the polymerization of butadiene or isoprene with balata, gutta-percha or rubber are recommended for bonding rubber to metals.<sup>280</sup> Synthetic rubber coating compositions may also be used in conjunction with water-sensitive adhesives in the preparation of stamps to be used on regenerated cellulose surfaces.<sup>281</sup> High polymers of isobutylene have been suggested as adhesives for safety glass, plywood and adhesive plasters.<sup>282</sup> Also, similar polymerization products when incorporated with kieselguhr and vulcanized in the presence of sulphur, zinc oxide, diphenylguanidine and naphthylamine, yield porous sheets for use in electrolytic cells.<sup>283</sup> Another preparation recommends the addition of rosin-ethylene oxide resins.<sup>284</sup>

Schmidt and Bock<sup>285</sup> have made use of polymerization products in the manufacture of colloidal solutions and pastes of insoluble dyes and pigments. The polymerizates, prepared in the usual way, are ground with the other components and the colloidal solution is formed by the subsequent addition of an organic solvent.

In order to impart additional rubber-like qualities to polymerized isoprene, Pratt<sup>286</sup> dispersed the material in water and coated the colloidal particles with albumin or casein. By adding a tanning agent the strength and toughness of the protein coating is increased.

## Chapter 10

### Resins from Petroleum

The possibility of employing petroleum as a cheap and abundant material for the production of resins has attracted considerable attention. Although it must be admitted that many of such products thus far obtained from petroleum are of an inferior grade, being dark in color and either soft or very brittle, at least one type, namely, that obtained by the polymerization of highly cracked gasoline, appears to have commercial significance.

Both neutral and acidic resinous bodies are present in natural petroleum though generally in relatively small proportions. Such substances are not strictly synthetic in the usually accepted sense of the word. They are discussed in this chapter, however, because of their possible utilization. Resins have been produced also by the condensation of petroleum distillates and residuums. Artificial asphalts belong to the class of oxidized petroleum and are only briefly mentioned since they are more fully discussed in other treatises. The conversion of petroleum hydrocarbons into resins by condensation with various reagents, e.g., formaldehyde, acids, or sulphur, has been suggested from time to time but apparently little progress has been made in this direction.

Cracking, or thermal decomposition, of petroleum distillates under proper conditions yields unsaturated hydrocarbons, monolefins and diolefins, which can be polymerized to resinous materials. Methods for the preparation of the latter are discussed in Chapter 9. Cracking petroleum hydrocarbons (for example, methane or natural gas) at very high temperatures gives resin-forming hydrocarbons including butadiene and, probably, also indene.

Oxidation of cracked hydrocarbon mixtures, such as cracked gasoline, proceeds spontaneously with the formation of resinous or gummy bodies. Treatment with refining agents (sulphuric acid, activated absorbent earths or zinc chloride) also converts unsaturated hydrocarbons of this type into resins. Since the latter substances are by-products of a large industry and could be available in great quantity, the separation of high-grade products, therefore, offers commercial possibilities. So far, however, little success apparently has attended efforts to utilize these by-products of refining.

#### RESINS OF PETROLEUM

The resinous and asphaltic constituents of petroleum consist of two classes, hydrocarbons and oxygenated compounds of high molecular weight.<sup>1</sup> The latter are composed of acidic bodies, neutral resins and asphaltic materials. Asphaltenes and carbenes often contain relatively large proportions of combined sulphur. Nevertheless, it is possible that neither sulphur nor oxygen is an essential constituent of such materials since an asphaltene of the formula  $C_{60}H_{100}$  and sp.gr. 1.023 has been isolated.

<sup>1</sup> D. Holde and R. Eickmann, *Petroleum*, 1907, 2, 1077; *Chem. Abs.*, 1908, 2, 1341. *Mitt. kgl. Materialprüfungsamt.*, 25, 8; *Chem. Abs.*, 1908, 2, 177.

The various types of resinous matter are differentiated by their solubility in organic solvents. Petroleum resins, which resemble vegetable resins in some of their properties, are extracted from distillates with 70 per cent alcohol.<sup>2</sup> Other extraction solvents which may be employed, particularly with lubricating or turbine oils, are acetone or castor oil<sup>3</sup> and a mixture of methyl alcohol and a hydroaromatic hydrocarbon such as cyclohexane.<sup>4</sup> These resins are described as oxygen- and sulphur-containing, terpene-like hydrocarbons. A more convenient method consists in treating the distillate with an absorption agent, e.g., animal charcoal or Florida earth. The latter is then extracted with benzene (to remove oil) and afterwards successively with ether, benzene and chloroform.<sup>5</sup> This procedure results in a partial fractionation of the resins, as indicated by a gradual increase in the specific gravity, viscosity and oxygen and sulphur contents, and decrease in proportions of carbon and hydrogen, of the extracted products.

According to Borodulin<sup>6</sup> the resinous constituents of petroleum distillates are (a) asphaltenes or (b) unsaturated hydrocarbons which are easily converted to resins, e.g., by polymerization or oxidation. The former are precipitated by the addition of petroleum ether<sup>7</sup> or are removed by Floridin or animal charcoal. Unsaturated hydrocarbons are resinated by treatment of the distillate with alcoholic sodium hydroxide,<sup>8</sup> sulphuric acid or formaldehyde (see discussion of formolites on pages 211-214).

Benzene, or petroleum ether, employed in the quantitative precipitation of asphaltenes should correspond to the following specifications:<sup>9</sup>  $d_{15}^{20}$  0.695-0.705, a boiling range of 65-95°C., and not more than 2 per cent be soluble in a mixture of 80 parts of 96 per cent sulphuric acid and 20 parts of fuming acid (20 per cent  $\text{SO}_3$ ). Other suggested precipitants are acetone,<sup>10</sup> ethyl acetate<sup>11</sup> and methyl ethyl ketone saturated with water.<sup>12</sup>

Carbenes and carboids are types of substances representing successive decomposition (or possibly condensation) products of asphaltenes.<sup>13</sup> Both possess a lustrous black color and resemble coal in appearance. Carbenes are insoluble in cold carbon tetrachloride and carboids in all organic solvents.

**Neutral Resins.** Neutral resins, asphaltenes, carbenes, and carboids form a series of oxygenated substances of increasing molecular complexity and diminishing solubility. Marcusson<sup>14</sup> considers petroleum resins are the first stage in the conversion of high-molecular-weight petroleum hydrocarbons into asphaltenes and describes them as being soluble in petroleum spirit, chloroform, carbon disulphide and benzol and having a specific gravity of about 1. Nitration indicates that both resins and asphalt are apparently polycyclic compounds. At 100°C. sulphuric acid changes these resins into insoluble sulphur compounds. Sulphuric acid and

formaldehyde react with the resins to form sparingly soluble precipitates. When heated for some time at 120°C. neutral resins become insoluble in petroleum ether, deep black in color and are transformed into asphaltenes.

Resinous components of lubricating oils are present to the extent of a few tenths of a per cent and can be separated from the hydrocarbons with alcohol and ether.<sup>15</sup> They are solid, oxygenated, lac-like bodies and may be a cause of gumming as their removal appears to decrease the gumming tendency of lubricants.

Neutral resins can be separated from oils and oxygenated materials by the following method.<sup>16</sup> The oil is washed with caustic soda solution to remove naphthenic and asphaltogenic acids. Asphaltenes are precipitated by the addition of petroleum ether and the residual oil is treated at 50°C. with silica gel in amounts determined by the resin content.<sup>17</sup> Fuller's earth is not as satisfactory as it adsorbs only 20 per cent as much resin and also effects polymerization. Adsorbed oil is removed from the gel with benzene and the resins are extracted with chloroform or a mixture of benzene and ethyl alcohol. The products obtained in this manner are neutral and only slightly unsaturated. Their molecular weights (in benzene) vary from 226 to 1112 and they form a series of oxygenated compounds of the formula<sup>18</sup>  $C_nH_{2n-m}O_p$ , in which  $n$  varies from 16 to 69,  $m$  from 8 to 48, and  $p$  from 1 to 3. Although unstable, these resins can be distilled at low pressure and give no evidence of colloidal behavior. However, they are easily transformed into asphaltenes by oxidation, which is accompanied by loss of hydrogen and further condensation. Sulphuric acid reacts with them to form asphaltenes and also sulphonates. Both neutral resins and asphaltenes are attacked by perbenzoic acid but not by iodine.<sup>19</sup>

An examination of the resins formed during the distillation of petroleum was made by Siebenek<sup>20</sup> who reported that these substances distilled over with steam at 400°C. in a yield of about 0.3 per cent. The crude materials had specific gravities greater than 1, softening points about 45° and flow points about 60°. Purification was accomplished by drying at ordinary pressure. Though not completely soluble in benzene, the dried resins were wholly soluble in benzene and analogous coal-tar distillates. By vacuum and steam distillation the crude material was separated into an oil (17 per cent of the total) and several resin fractions as follows:

Resin 1 (11 per cent).

Resin 2 (29 per cent), softening at 53°C. and flowing at 70°C.

Resin 3 (13 per cent), softening at 55°C. and flowing at 72°C.

Resins 2 and 3, constituting 42 per cent of the crude, were dark yellow in color and stated to be valuable technically.

Tweddle<sup>21</sup> suggests treating an orange-colored, resinous, oily residue from the distillation of crude petroleum with benzene, thereby obtaining a yellow crystalline precipitate which is termed petrocene. This substance (sp.gr. 1.204) melts at 420-430°C., but if heated to higher temperatures it sublimes and distils, giving off brilliant yellow fumes. Its spectrum is somewhat similar to that for anthracene, possibly indicating petrocene to be a polycyclic hydrocarbon. By appropriate treatment it may be transformed into dyes and other coloring materials.

Resins are prepared from heavy residual hydrocarbons, of petroliferous origin, by submitting the latter to distillation at low pressures (to remove oily constituents) and extracting with a hydrocarbon solvent, e.g., kerosene or naphtha.<sup>22</sup> The last operation precipitates asphaltenes. Aqueous emulsions of such oil-soluble resins are proposed as sizing agents for paper, for impregnation of porous paper and in the manufacture of laminated paper and board.<sup>23</sup>

Incorporation of tar pitch and picoline with petroleum residues, by the application of heat, to give synthetic resins is described by Maslyanskii.<sup>24</sup>

**Asphaltenes.** These are present in crude petroleum, particularly in the higher-boiling fractions and residuums from distillation. They are formed probably from the aromatic constituents of an oil by condensation and polymerization, asphaltic resins being an intermediate stage. Asphaltenes having the following composition, carbon 71.6 per cent, hydrogen 6.3 per cent, oxygen 13.3 per cent and sulphur 8.1 per cent, were prepared by heating naphthenes or paraffins with sulphur and then oxidizing with air.<sup>25</sup> The so-called asphaltenes obtained from acid sludge differ from normal asphaltenes in being soluble in basic solvents. They are coagulated by heating to 100°C. and are probably oxonium compounds derived from sulphuric acid.

Asphaltenes are brown to black in color, have no apparent melting point and decompose to gas and coke at 300°C. They are insoluble in petroleum ether, alcohol, water and most other solvents but dissolve in carbon tetrachloride. Solution is preceded by swelling of the material and results in the formation of a viscous liquid. The latter appears to be colloidal and highly dispersed and as stable as aqueous gelatin solutions. Asphaltenes are lyophile colloids with respect to aromatic hydrocarbons, halogenated hydrocarbons, carbon disulphide and petroleum tars and are lyophobic with respect to paraffin hydrocarbons and naphthenes.<sup>26</sup> Their molecular weights are about 5000-6000 and they contain appreciable proportions of oxygen and usually some combined sulphur. Substances of this type precipitated from Grozny petroleum contained 85.5 per cent carbon, 6.8 per cent hydrogen, 7.7 per cent oxygen and some sulphur and had a density of 1.145.

Oxidation of the higher fractions of petroleum with air or oxygen at elevated temperatures yields asphaltenes. The work of Chernozhukov,<sup>27</sup> however, indicates that the presence of sulphur compounds is essential during oxidation. Thus, oxidation of liquid paraffin, free of sulphur, by oxygen at 250°C. and 12 atmospheres pressure for 2 hours gave a yellow oil from which a flaky sediment could be precipitated, but no asphaltenes or carbenes were formed. Similar treatment of sulphur-free oils to which sulphur was added yielded synthetic asphaltenes possessing the properties of natural asphaltenes but of lower molecular weights. Various asphaltenes were prepared by oxidation of sulphur-containing crude oils with air or oxygen under pressure. Those from a turbine oil distillate had the empirical formula  $C_{172}H_{176}O_{11}S$ , and those from a light spindle oil the formula  $C_{136}H_{140}O_{12}S$ . Chernozhukov concluded that sulphur compounds of unknown constitution and of various stages of oxidation are responsible for the production of asphaltenes. The important role of sulphur compounds in this respect is indicated also by the observation that resinous deposits, obtained from Boryslaw (Galicia)

paraffin oils on storage, had a sulphur content of 2.5 per cent whereas the crude oil contained only 0.1 per cent sulphur.<sup>28</sup>

Elimination of asphaltenes and other dark-colored substances from natural or artificial asphalts furnishes lighter-colored products which may be employed in the manufacture of asphalt paper, lacquers, varnishes or paints.<sup>29</sup> Purification consists in the addition of a precipitant, such as aromatic-free gasoline or pentane, to the molten crude material. Further treatment of the asphalt solution with decolorizing agents, e.g., bleaching earths, is also advantageous. A combination of physical and chemical methods may be used. For example, after dilution with the precipitant the solution of asphalt is subjected to the action of sulphuric acid, anhydrous aluminum chloride, ferric chloride or boron fluoride. The latter procedure converts any dissolved asphaltenes into insoluble substances.

Resinous or asphaltic materials are precipitated from mineral oils by warm, dilute sulphuric acid (1-10 per cent soln.)<sup>30</sup> or by allowing the oil to stand in contact with concentrated aqueous solutions of heavy metal salts, especially the chlorides.<sup>31</sup>

Moderate hydrogenation of asphaltenes, particularly in the presence of a hydrocarbon solvent, transforms them into resins or resin-like bodies.<sup>32</sup>

Discussion of more complex oxygenated materials, including carbenes, carboids and asphalts, are beyond the scope of this text. Resins made by oxidation of various petroleum fractions are described later.

**Petroleum Acids.** Carboxylic acids in petroleum, which are comprehended under the generic name of naphthenic acids, are of technical and scientific interest.<sup>33</sup> These acids differ considerably in physical properties, depending upon their origin. Those of low molecular weight are volatile oils of penetrating odor and consist mainly of monocarboxylic acids containing one cyclopentane ring. Bicyclic and possibly other polycyclic monocarboxylic acids are present also in Rumanian, German, Californian and Texas crudes.<sup>34</sup> High molecular weight acids, such as those from lubricating stocks, are viscous liquids and, in some instances, semi-solid materials.

Acids isolated from certain lubricating oils of American origin are of special interest.<sup>35</sup> These are monocarboxylic acids of the series  $C_nH_{2n-6}O_2$  and  $C_nH_{2n-8}O_2$  ( $n$  varying from 16 to 25) having molecular weights ranging from 250 to 376. They are viscous liquids which do not solidify at  $-30^\circ C.$ , are non-volatile in steam and do not absorb oxygen or "dry" on exposure to air. Salts of these acids are soluble in gasoline, ether and carbon tetrachloride while the lithium, ammonium, potassium, sodium and magnesium salts are soluble in water. The acids are prepared in the following manner.

Gasoline vapors are passed into alkali sludge obtained by washing acid-treated

<sup>33</sup> Asphaltic acids and asphaltic anhydrides are described by V. Kalchevsky and S. C. Fulton (*loc. cit.*) but little is known about them. They are sparingly soluble in light naphtha, have relatively high specific gravities and are unstable. They are readily distinguished from true naphthenic acids which are stable and saturated in character. See also J. Marcusson, *Z. angew. Chem.*, 1918, 29, 346, *J.S.C.I.*, 1918, 35, 1099.

lubricating distillates. This results in a separation into oil and water layers and is facilitated by the addition of 0.1 per cent by volume (on the sludge) of a saturated solution of sodium chloride. Dissolved resins are removed by the gasoline-oil layer. The oil-free soap solution (water layer) is concentrated and then cooled to  $-5^{\circ}\text{C}.$  at which temperature precipitation of soap occurs. This may be hastened by cooling to slightly lower temperatures. The soap is decomposed by acidification or by hydrolysis with steam under pressure and the free acids further purified by distillation under reduced pressure. Acids obtained directly from the soap have an acid number of about 103. The acid number of the distilled product is usually greater. For example, distillation of the acids under 4 mm. pressure yielded the following fractions:

Fraction	Temperature	Acid No.
1 . .	Up to $180^{\circ}\text{C}.$	187
2	$180\text{--}190^{\circ}\text{C}.$	174
3 .	$190\text{--}200^{\circ}\text{C}.$	160
Residue	Acid + Resins	61

Another method of purification consists in acidifying the aqueous solution of alkali salts, adding xylene, and removing water by distillation of the mixture.<sup>85a</sup> The residue is separated into acids and insoluble colloidal hydrocarbons by extraction with ethyl alcohol.

In the preparation of metallic derivatives either the purified soap or acids derived therefrom, without preliminary distillation, may be used. Thus, addition of a solution of calcium chloride to an aqueous solution of the soap gives the calcium salt which is a light-colored, sticky, tenacious mass practically insoluble in water and can be washed free of entrained salts by agitation with water.<sup>86</sup> It is slightly soluble in methyl or ethyl alcohol and acetone, very soluble in ethyl acetate, carbon tetrachloride, gasoline, benzene or ether and dissolves to some extent in turpentine and linseed oil. The calcium salt may be used in numerous ways, for example, as a water-proofing material, adhesive, wood filler, grafting wax, cement or varnish. The barium salt, though somewhat darker in color, possesses similar properties.

Precipitation of the calcium salt in the presence of water-soluble dyes leads to the formation of color lakes which are insoluble in water but soluble in other solvents, such as ethyl acetate or petroleum ether.<sup>87</sup> These lakes, and also those similarly prepared from the barium salt, may be employed in the manufacture of lithographic and printing inks, colored paints and varnishes.

Of the other metallic derivatives of these complex acids, the copper, chromium, and nickel salts which are green in color, and the cobalt salt, which is purple, may be employed in paints. The manganese salt is mahogany in color and hardens on exposure to air. Lead and zinc salts, though darker in color, possess properties somewhat similar to the corresponding barium and calcium compounds.

Naphthenic acids, obtained from the waste lyes in refining lubricating oils from Galician and Rumanian crudes, are described as brownish-black, resinous substances,<sup>88</sup> readily soluble in benzene. Samples of each exhibited acid numbers of 87 and 157, respectively. Metallic derivatives of some monocarboxylic naphthenic

<sup>85a</sup> G. Alleman, U. S. P. 1,931,855, Oct. 24, 1933, to Sun Oil Co.; *Brit. Chem. Abs.* B, 1934, 615.

acids, particularly the lead salts of trideca-, tetradeca-, and pentadeca-naphthenic acids from Japanese crudes, are resinous in appearance.<sup>39</sup>

In refining crude petroleum distillates, addition of sufficient alkali before distillation retains the natural emulsifying agents (naphthenic acids or acid resins) in the residues.<sup>40</sup> The latter may be dispersed directly in water, or acidified (to liberate the organic acids) and then emulsified in dilute caustic soda solution.

Materials resembling rubber or linnoxyn may be prepared in the following manner.<sup>41</sup> A slightly alkaline solution of an alkali naphthenate is treated with a solution of aluminum or chromium salts until a salt of hexanaphthenic acid (o-methylcyclopentanecarboxylic acid) begins to precipitate. In this way the unpleasant odor of the naphthenate is said to be removed. The naphthenates so obtained, when heated to 170°C., yield very viscous solutions resembling solutions of rubber. At higher temperatures (e.g., 300°C.) a horny mass is produced which gives mobile solutions in turpentine, pine oil and solvent naphtha.

Zernik<sup>42</sup> is of the opinion that the unpleasant odor associated with naphthenic acids is due possibly to low-boiling fractions and unsaponifiable constituents in the crude product. Such impurities can be eliminated by fractional distillation and treatment of the (naphthenic) soap solutions with inert solvents. Distillation involves cautious dehydration and fractionation in vacuo (without superheated steam) from vessels containing aluminum cooling coils. Salts of the purified acids may be employed in making resins and lacquers.

A number of metallic salts of naphthenic acids have been proposed for various purposes. For example, lead salts are suggested as driers for varnishes,<sup>43</sup> those of aluminum and chromium as siccatives,<sup>44</sup> and others such as iron, zinc or calcium for improving the properties of electrical insulating materials,<sup>45</sup> or when mixed with fillers (e.g., lithopone, cork meal, sawdust or powdered metals) for the manufacture of artificial leather, sealing wax or adhesives.<sup>46</sup> Other uses for metallic naphthenates include incorporation with ceresin or paraffin or carnauba wax to yield synthetic resins and waxes,<sup>47</sup> addition to lubricating or other oils to increase their viscosity<sup>48</sup> and act as antioxidants,<sup>49</sup> as emulsifying agents for petroleum distillates<sup>50</sup> and residues,<sup>51</sup> and catalysts for the polymerization of drying or semi-drying oils.<sup>52</sup> Calcium naphthenate is said to be a stabilizing agent for coating compositions containing a polysaccharide ester and an alkyl naphthenate.<sup>53</sup> Condensation products of naphthenic acids and amino-alcohols (for example, mono-, di- or tri-ethanolamine) may be employed as dispersing agents in the dyeing of

cellulose acetate fabrics.<sup>54</sup> Arylamino derivatives have been prepared by the reaction of aromatic amines on naphthenic acids.<sup>55</sup> The latter acids, in chloroform solution, react also with hydrazoic acid to yield amines.<sup>56</sup>

Naphthenic acid anhydrides, made by heating the acids with acetic anhydride, are soluble in ether and benzene but very much less so in cold 95 per cent alcohol than naphthenic acids.<sup>57</sup> The anhydrides react with cellulose, in the presence of pyridine, to give the corresponding esters.

#### RESINS BY OXIDATION OF PETROLEUM

Oxidation of petroleum and petroleum distillates gives rise to a wide variety of products including resins and asphaltic materials, depending upon the conditions of oxidation. Thus far, however, no high-grade resin appears to have been made by such methods. Brooks<sup>58</sup> considers that in view of the nature of copal acids and those of other natural resins, there is a distinct promise that polycyclic hydrocarbons of lubricating oil distillates and the heavier fractions of gas oil can be oxidized to resins. No such procedure has been developed yet which does not give black asphaltic products.

From the viewpoint of synthetic resins, the most interesting reactions are those yielding asphaltenes and asphalt-like bodies and carboxylic acids. Vapor-phase oxidation of heavy petroleum distillates gives acids of the aldehyde or hydroxy-aldehyde type mixed with aldehydes of various molecular weights. On saponification with alkalis, brown or yellow resins are formed by condensation.<sup>59</sup> If the soaps are separated and treated with an excess of dilute hydrochloric acid, resinification of the liberated acids takes place.<sup>60</sup> These latter resins are suggested as bases for paint and varnish mixtures.

Resinifiable acids are obtained by catalytic oxidation of hydrocarbon oils in the liquid-phase. For example, by air-blowing petroleum in the presence of alkalis Schaal<sup>61</sup> obtained liquid acids which, on vacuum distillation, furnished a residue of a resinous nature. Solid acids from this same procedure formed asphalt-like masses with calcium or magnesium oxides. Esters of the latter acids were somewhat resinous in character and could be used in making varnishes or as substitutes for waxes, pitch or asphalt. Charitschoff<sup>62</sup> points out that Schaal's method yields not only naphthenic acids but also viscous polynaphthenes which are probably bicyclic condensation products. These polynaphthenes seem to be pseudo-acids, apparently tribasic although they contain only four atoms of oxygen. As they are easily decomposed to resinous substances by heat or the action of concentrated alkaline solutions they have been called asphaltogenic acids.

High-boiling petroleum fractions (lubricating distillates, turbine or transformer oils) give resins and asphaltic substances, which are either neutral or acid in character, on exposure to air. Three classes are recognized in the case of lubricating oils;<sup>63</sup>

(1) Asphaltic resins, soluble in oil and petroleum ether and absorbed by charcoal and fuller's earth, which are responsible for the discoloration and increase in viscosity of the oil.

(2) Asphaltenes, which are insoluble in petroleum ether and are formed by oxidation of the resins.

(3) "Varnish," which is the final oxidation product and is insoluble in all the usual solvents.

It is doubtful, however, whether the above classification is complete since acidic resins are often produced. In the sludging of turbine oils, for example, complex naphthenic acids probably containing hydroxy, keto, or aldehydic groups are formed. A turbine oil sludge investigated by Salathe<sup>94</sup> contained 13.6 per cent of complex naphthenic acids having 50 or more carbon atoms per molecule. In the dry state these acids were brown, hard, brittle resins and were soluble in the lower aliphatic alcohols, chloroform, pyridine, aniline, benzene and slightly soluble in ether. The calcium salt was obtained as a brown gelatinous precipitate.

Oxidation of tar oil, paraffin, or montan wax also furnishes acids of high molecular weights. By treating tar oil (free of phenol) at 200°C. with air under 30 atmospheres pressure, in the presence of sodium carbonate, Schneider<sup>95</sup> secured a 55 per cent yield of liquid syrupy acids whose properties were similar to those of Charitschoff's polynaphthenic acids. In the absence of alkali about one-half of the tar oil was precipitated as a solid asphalt. Lignite tar gave mainly monobasic fatty acids. Using 200 g. of paraffin, 800 cc. of 2.5*N* sodium carbonate solution, 30 atmospheres pressure, a temperature of 170°C. and 200 l. of air per hour, 141 g. of paraffin were oxidized giving 46 per cent of water-insoluble acids. These were brown in color and had an average molecular weight of 271. From American paraffin, acids of the formula  $C_nH_mO_2$  ( $n = 13, 15, 17$  or  $19$ ) were obtained. In the latter instance, reaction was accelerated by salts of iron, copper and manganese, but not by alkalis. Montan wax was difficult to oxidize and yields were low. Schmidt<sup>96</sup> exposed paraffin wax to a blast of air for a considerable period of time at 100-120°C., producing resin acids and fatty acids. Rapidity of reaction is increased by addition of mercuric oxide or previously oxidized wax.

Chernozhukov<sup>97</sup> states that the oxidation products (of petroleum) having acid values between 60 and 110 form resinous bodies by loss of carbon dioxide and subsequent condensation of the resulting unsaturated hydrocarbons. Also condensation of aldehydes and other intermediate oxidation compounds may take place. Reaction of acids with aldehydes in the presence of amines is a method suggested by Petrov.<sup>98</sup>

The dark-colored liquids obtained by pressing crude acids (from oxidation of paraffin wax) are acidic in character and insoluble in petroleum ether. These may be combined with glycerol, or other polyhydric alcohols, to give materials resembling linnoxyn or artificial rubber.<sup>99</sup> Catalysts, e.g., lead oxide or sulphur, may be used also. To illustrate, 150 parts of the liquid acids are mixed with 19.3 parts of glycerol and heated for 30 minutes at 170-210°C. A dark, tenacious, non-greasy elastic mass is formed which is soluble in alcohol, petroleum ether and acetone. Addition of 15 parts of sulphur to the above mixture before heating results in a deep-black, crumbly mass. The liquid acids may be substituted by unsaturated aliphatic acids made by dehydration of the oxidation products of paraf-

fin hydrocarbons or waxes.<sup>70</sup> Reaction then takes place best in the presence of a solvent, such as a petroleum distillate. Air or oxygen may be passed into the mixture during heating.

Artificial shellac is prepared by Burwell<sup>71</sup> in the following manner:

A fuel oil distillate, of 33-18° Bé, is oxidized at 130-160°C. and 150-350 atmospheres pressure with air or oxygen-enriched air. About 0.1 per cent of iron, copper, or manganese oleate is used as catalyst. The initial products of the reaction consist of petroleum-soluble acids and petroleum-insoluble hydroxy acids.<sup>72</sup> Reaction is continued until the concentration of the latter reaches 20-40 per cent. Three layers are formed, the top consisting of unchanged hydrocarbons and petroleum-soluble oxidation products and the bottom of an aqueous solution of acids. The middle layer containing hydroxy acids is separated and distilled at a pressure of 10-20 mm. and temperature of 140-275°C to remove the more volatile constituents. Employment of the higher distillation temperatures furnishes harder and more brittle resins, but the less brittle, even tacky, resins have significant dielectric properties.

Air-blowing of alberta bitumen results in the formation of rubber-like products.<sup>73</sup> During blowing there is a decrease in the proportions of asphaltous acids and anhydrides, oily constituents and resins, and an increase in the melting point of the material. At the same time the molecular weight of the resins increases from 733 to 1012 and that of the asphaltenes from 2219 to 4690. Reactions appear to be essentially dehydrogenation, i.e., removal of hydrogen as water, followed by polymerization. The latter is accelerated by the sulphur content of the bitumen.

The possibility of preparing resins from high-boiling petroleum distillates by treatment with ozone is indicated by the work of Koetschau.<sup>74</sup> By subjecting a transformer oil (sp.gr. 0.915 and molecular weight, in benzene, 293) to the action of ozone at 12°C. a 25 per cent yield of ozonides was obtained. These were solid or semi-solid substances, insoluble in petroleum ether and having a mean molecular weight of 663. The latter figure corresponds closely with the calculated value of the dimeric ozonide,  $(C_{10}H_{20}O_6)_2$ . Unless kept at low temperatures, the ozonides decompose and redden. Ozonization of spindle oils, from Texas and Pennsylvania crude oils, yielded a flocculent, white precipitate which, at temperatures of 21°C. or higher, gradually changed to a red-colored resin. Stable products were obtained from oils previously refined with aluminum chloride, the latter procedure removing a large proportion of the sulphur compounds.

Mention has been made of the important role played by sulphur compounds in the formation of asphaltenes from heavy oils.<sup>75</sup> Sludge formation in transformer oils by oxidation apparently is markedly accelerated by salts of sulphonic acids.<sup>76</sup> Certain metals, for example, copper and lead, increase the rate of development of both resins and sludge in the same types of oil.<sup>77</sup> The changes taking place in petroleum residues and tars on blowing with air were investigated by Marcusson and Picard.<sup>78</sup> Oxidation and polymerization were not influenced by catalysts such as manganese dioxide or fuller's earth possibly because the latter were poisoned by sulphur compounds.

Resinous substances are produced by oxidation of petroleum hydrocarbons with certain chemical reagents. When liquid paraffin of the German Pharmacopoeia is oxidized in sulphuric acid with potassium permanganate a soft resin is obtained. If first oxidized in alkaline solution with permanganate and then further in acid solution a brittle resin softening at 75°C. is formed. This resin is partly soluble in hot caustic potash solution, is easily soluble in benzene, chloroform, turpentine, ether, alcohol and acetone, and is difficultly soluble in carbon tetrachloride, methyl alcohol and heavy benzene.<sup>79</sup> Chlorine resinifies paraffin oil, addition of potassium bichromate favoring the production of solid material. If bichromate and hydrochloric acid are used, the reaction is likely to become violent and requires careful attention. By heating 2 parts of liquid paraffin oil with 2.5 parts of nitric acid (sp.gr. 1.486) for 10 hours at 90-100°C., then adding 0.5 part of nitric acid and heating for 2 hours longer, solids were obtained. These, when dissolved in 15 per cent caustic potash solution and acidified with hydrochloric acid, gave a 75 per cent yield of resinous brown fatty acids. By employing this same procedure, paraffin wax yielded a mass of ointment-like consistency. Yellow vaseline furnished both a solid and an ointment-like resin, the latter containing no acid constituents.

After partial neutralization and esterification of the acids in montan wax, resulting from bleaching with chromic acid, the mass can be incorporated with iron powder to give products applicable to the manufacture of magnetic cores.<sup>80</sup> A varnish, which however is not very fast to moisture, is made by dissolving the calcium salt of oxidized vaseline in turpentine.<sup>81</sup>

The work of Bestuzhev<sup>82</sup> indicated that mild oxidation of lubricating oils with nitric acid converted the naphthenic constituents mainly to acids. When concentrated nitric acid and elevated temperatures were employed oxidation was more energetic and yielded polymerization products, resins and asphaltic compounds.

According to Kleiber and Gilardi<sup>83</sup> a type of synthetic rubber is made in the following manner:

Five l. of American petroleum are agitated for 4 hours with 1.25 l. of nitric acid (sp.gr. 1.4). The reaction mixture is washed with water and alkali, and repeatedly distilled from rosin. The residue may be used as a substitute for copal. The distillate is heated with alkali (125 g. of sodium hydroxide in 1.25 l. of water) at 156°C. and a pressure of 5-6 atmospheres for 1 hour. Three layers are formed. To 5 l. of a mixture of the two upper layers, at 40°C., are added 2 kg. of acetic acid and 1.25 l. of formaldehyde, in small portions, followed by 350 g. of crude rubber. Heating is continued for 8 hours at 60°C. Treatment of the resulting syrupy liquid with 4 volumes of acetone or alcohol precipitates a vulcanizable, elastic mass.

Rubber-like bodies may be obtained by oxidation of hot oil or pitch with air in the presence of an oxygen-transmitter such as the oxides of nitrogen.<sup>84</sup> A catalyst, e.g., nitric acid and a little manganese dioxide may be employed also.

#### RESINS BY CONDENSATION WITH VARIOUS REAGENTS

**Reaction with Formaldehyde.** Reaction of certain cyclic and unsaturated hydrocarbons with formaldehyde, in the presence of sulphuric acid, gives the so-

called "formolites" which are solids, often of a resinous nature.<sup>85</sup> This reaction was discovered by Nastuykov,<sup>86</sup> who proposed it as a quantitative method for the determination of aromatics. The test as originally advocated by Nastuykov involved mixing the petroleum distillate with an equal volume of concentrated sulphuric acid, the latter being added in small portions, and then adding slowly with good agitation one and a half volumes of aqueous formaldehyde. A precipitate was formed which after washing with petroleum ether and ammonia water was a brown powder. These proportions were satisfactory when the formolite was less than 50 per cent of the weight of the oil; if greater, then the proportions of reactants suggested were 1:1:2.<sup>87</sup> If less sulphuric acid was employed the product varied in character from the usual amorphous insoluble powder through soluble solid to soluble liquid materials. Highest yields were obtained by carrying out the reaction at about 0°C.<sup>88</sup>

The above procedure was modified later,<sup>89</sup> and proportions of oil, acid and formalin were changed to 1:4:2. After condensation, the mixture was refluxed on a water bath for 1 hour, and then diluted with 5 volumes of water. Any clear supernatant oil was withdrawn. After heating again for 1 hour, in a current of steam, the precipitate was filtered, washed and neutralized as before, dried and weighed. To the weight in grams add 5.25 per cent (to account for persistence of moisture and change in weight due to reaction with formalin) to obtain formolite numbers. Such alterations in method are said to yield a powder-like mass which is never sticky. The solubility of formolites in benzene and their insolubility in other solvents (alcohol, chloroform, carbon tetrachloride, acetone and ether) appear to increase with the boiling point of the oil.<sup>90</sup>

Severin<sup>91</sup> investigated the effects of the sulphuric acid-formaldehyde mixture on different types of hydrocarbons. Paraffins (normal hexane or octane) and saturated naphthenes (methyl or dimethylcyclohexane) did not react with this reagent. Olefins (amylene or octylene) yielded a reddish-brown syrupy liquid and unsaturated naphthenes (cyclohexane or dimethylcyclohexane) gave reddish-brown precipitates soluble in water. Aromatics formed water-insoluble precipitates which were red in color except those from naphthalene and anthracene, which were deep green and yellowish green, respectively. It was suggested that olefins be removed from petroleum fractions (boiling below 200°C.) with 3 per cent of sulphuric acid before formolite numbers are determined. Also distillates with a high content of aromatics should be diluted with paraffinic benzine.<sup>92</sup>

Tauss<sup>93</sup> reports that conjugated diolefins, e.g., methylbutadiene, respond to the formolite reaction. Completely substituted aromatics, such as hexamethyl- or hexaethylbenzene, do not yield formolites, thus apparently indicating that only hydrogen atoms attached to the benzene nucleus combine with formaldehyde. He also proposed the use of trioxymethylene instead of aqueous formaldehyde as the latter so dilutes the sulphuric acid as to impair its value as a condensing agent.<sup>94</sup>

<sup>85</sup> Some German chemists comprehend under the term formolite all resins yielded by the action of formaldehyde on any substance capable of reacting with this aldehyde to form resinous bodies. The resinifying reactions of formaldehyde are so varied and the products so diverse, physically and chemically, that such a classification is considered by the author to lead to much confusion.

<sup>93</sup> J. Tauss, *J. prakt. Chem.*, 1919, 99, 276; *Chem. Abs.*, 1920, 14, 934.

<sup>94</sup> A critical analysis of the formolite reaction is given by J. Hosek, *Chem. Obzor.*, 1929, 4, 67; *Chem. Abs.*, 1929, 23, 2813.

It is interesting to note that the procedure of Richardson,<sup>96</sup> in which trioxymethylene is employed, gives rise to a gummy material insoluble in concentrated ammonium sulphate solution but soluble in water.<sup>96</sup>

A further modification of the formolite reaction is proposed by which various properties of the oil can be determined.<sup>97</sup> The first formolite number,  $F_1$ , is obtained as previously described. The second number,  $F_2$ , is obtained by treating the first formolite with petroleum ether in the cold, filtering, drying at 100-105°C. and weighing.  $F_1 - F_2$ , or  $a$  is the true potential content of lubricating oil. The second formolite is treated in the same way with chloroform to give  $F_3$ , or the real formolite number.  $F_2 - F_3$ , or  $b$ , represents the resin content of the oil. Formolite values up to  $F_7$  are calculated. Differences between these indicate the proportions of total unsaturated cyclic hydrocarbons, light lubricating fractions, asphaltic unsaturated hydrocarbons and saturated hydrocarbons. The Engler viscosity,  $E$ , may be calculated according to the formula

$$\frac{(E + b)}{(F_2 + 2b - 3.5)} = C$$

in which the values of  $C$  (a constant), at 100°C. for cylinder oils and "viscosines" and at 50°C. for machine oils, are 0.20, 0.22 and 0.29, respectively.

Formolites are obtained by treating (unsaturated) fractions from the distillation of *Ostaschkov sapropel*<sup>98</sup> with an equal volume of concentrated sulphuric acid and 0.5 volume of 40 per cent formalin.<sup>99</sup> These are brown, amorphous products, insoluble in organic solvents and have no definite melting points. Such resins from sapropels are suggested as electrical insulating materials, as they are reported to possess the property of adhering to metals without cracking when the latter are bent.<sup>100</sup>

Application of the formolite reaction in the refining of lubricating or burning oils is described by Nastyukov.<sup>101</sup> The crude distillate is treated with a mixture of 4 volumes of sulphuric acid and 2 volumes of 40 per cent formaldehyde. The reaction mass is diluted with water, steam distilled to remove volatile products, and filtered. The precipitate is washed, neutralized and dried and the resulting brown powder freed of adsorbed oil by extraction with benzene. This formolite, alone or mixed with synthetic resins or other plastics, may be employed in the manufacture of molded articles.<sup>102</sup>

Ormandy and Craven<sup>103</sup> found when cracked gasolines are refluxed with formalin, in the presence of an electrolyte, brown resins are formed. These varied in consistency from a sticky oil to a hard gum. A typical reaction mixture consisted of 5 g. of gasoline, 5 cc. of formalin and 5 cc. of hydrochloric acid (sp.gr. 1.16). Heating for about 2 hours was necessary. The reaction product was isolated by evaporation of the gasoline and drying the residue in a steam-oven. Yields were roughly proportional to the bromine number of the hydrocarbon liquid, though small amounts of resins were obtained from benzene and its immediate homologues. Condensa-

tion with formaldehyde converted only a part of the unsaturated hydrocarbons to resins in one treatment. An increase in the proportion of formalin, or substitution of formalin by paraformaldehyde, resulted in a smaller yield of products. Some of the results obtained by these investigators are given in Table 24.

TABLE 24.—Resins from Cracked Gasoline and Formaldehyde.

	Bromine No.	Yield of Resin, %
Cracked Gasoline No. 1 .	76 2	35 8

Benzene . . . . .	0 2	0 5
Toluene . . . . .	Nil	1 5
m-Xylene . . . . .	Nil	6 8

**Reaction With Methylal.** According to Herr,<sup>104</sup> methylal yields condensation products of the formolite type with the aromatic constituents of petroleum or its distillates. Methylal is said to be superior to formaldehyde because it acts as a solvent as well as a condensing agent and is more sensitive, being capable of detecting 0.05 per cent of benzene.

One part by weight of the oil dissolved in 2 parts of methylal and 4 parts of sulphuric acid introduced as a fine stream gives a product which is separated by pouring the liquid mixture into water, neutralizing with ammonia and filtering. If the liquid is kept cool during reaction, the product is soluble in chlorobenzene. On the other hand if the liquid is allowed to become hot and finally is heated on a water bath for half an hour, a large yield of an insoluble material is obtained. A rough rapid comparative determination of the unsaturated constituents of an oil can be made by taking a 2 cc. sample in a graduated stoppered bottle, adding 4 cc. of methylal dissolved in 10 cc. of light petroleum, then 2 cc. of sulphuric acid and shaking for one minute. After standing for half an hour, the volume of the precipitate is read directly.

An investigation of the formolite reaction was made by Dobryanski,<sup>106</sup> using a solution of 1 g. of benzene in 9 cc. of benzene, and methylal instead of formaldehyde. The optimal proportion of reactants was 5 cc. of methylal, 7.5 cc. of 93.6 per cent sulphuric acid and 10 cc. of the benzene solution. The highest formolite number was obtained in 10 minutes, and an excess of the acid should be avoided. Formolites differed qualitatively according to the conditions and proportions of reactants. The condensation product obtained when the quantity of mixture employed was considerably less than that mentioned above was designated  $\alpha$ -formolite. The dark-colored condensate obtained by treatment with an excess of sulphuric acid was called  $\gamma$ -formolite. This became a horn-like mass when dried.  $\beta$ -Formolite was secured under optimal conditions. The high sensibility of the formolite number against the quantity and concentration of aromatic hydrocarbons renders the determination of the latter in unknown mixtures problematical. At best the number can be used for comparative purposes only.

**Reaction With Metallic Halides.** Anhydrous stannic chloride<sup>106</sup> polymerizes oxygenated bituminous constituents of petroleum. Only a small amount of the reagent is required to produce a bulky precipitate from a heavy crude distillate. This chloride converts tars into solid asphaltum or pitch-like substances. For ex-

<sup>104</sup> V. F. Herr, *Chem.-Ztg.*, 1910, 34, 893; *J.S.C.I.*, 1910, 29, 1094. See also M. Borodulin, *Neft Khoz.*, 1923, 14, 393; *Chem. Abs.*, 1923, 22, 2262.

<sup>105</sup> A. Dobryanski, *Neft Khoz.*, 1927, 12, 57; *Chem. Abs.*, 1928, 22, 4239. Cf. A. Dobryanski and M. Olevskii, *Neft Khoz.*, 1927, 12, 227; *Chem. Abs.*, 1928, 22, 4240.

<sup>106</sup> G. Torossian, *Ind. Eng. Chem.*, 1921, 13, 904.

ample, pine tar is changed into a solid, lustrous, pitch-like body on treatment with 10-15 per cent of stannic chloride. Reaction is very vigorous and highly exothermic.

As previously mentioned, leNobel<sup>107</sup> employed ferric chloride, anhydrous aluminum chloride or boron fluoride to eliminate asphaltenes, as amorphous insoluble materials, from asphalt. Other halides suggested as precipitants for asphaltic or gummy compounds from lubricating oils include titanium chloride, zinc chloride and stannic bromide dissolved in liquid sulphur dioxide.<sup>108</sup>

Stable resins are prepared in the following manner from petroleum tar.<sup>109</sup> The tar is distilled at low pressures (1 mm.) to remove oily material and the residue is treated for 2 hours at 100-180°C. with 1-10 per cent of aluminum chloride. Reactive constituents are condensed or polymerized. The resin is purified either by extraction with a selective solvent or by treating its solution in a hydrocarbon solvent with sulphuric acid and evaporating the solvent after neutralizing.

Zelinskii and Smirnov<sup>110</sup> heated the heptanaphthene fraction (b.p. 101-102°C. at 740 mm.) from Baku petroleum with aluminum chloride in sealed tubes to temperatures of 100-140°. The reaction products consisted of a gas (mainly isobutane), high-boiling liquid unsaturated hydrocarbons and a yellow non-distillable resin.

**Reaction With Sulphur and Sulphur Chloride.**<sup>111</sup> When saturated hydrocarbons are heated with sulphur to temperatures above 200°C. reaction occurs yielding hydrogen sulphide and resinous and asphaltic substances of unknown constitution. Though some cyclic hydrocarbons, such as cyclohexane, are stable to sulphur at temperatures up to 200°C. many high-molecular-weight hydrocarbons and heavy petroleum distillates are vigorously attacked under these conditions.<sup>112</sup> Indications are that both condensation and dehydrogenation reactions take place.<sup>113</sup> For example, cyclic sulphur-containing compounds are obtained by heating sulphur and octane in sealed tubes to 270-280°C. Their formation may be represented by:

Under similar conditions hexylene and sulphur gave the following compounds:  $\text{C}_6\text{H}_{12}\text{S}$ , boiling point 40-41°C. at 10 mm.;  $\text{C}_8\text{H}_{16}\text{S}$ , boiling point 112-113°C. at 10 mm.;  $\text{C}_{10}\text{H}_{20}\text{S}$ , boiling point 128°C. at 10 mm.; and an asphaltic residue whose composition corresponded to the formula,  $\text{C}_{24}\text{H}_{32}\text{S}_2$ .<sup>114</sup> Resinous or asphalt-like substances resulting from sulphurizing paraffin hydrocarbons may be added to rubber before vulcanizing.<sup>115</sup>

Reaction of sulphur monochloride with saturated hydrocarbons yields chlorinated

<sup>115</sup> H. Klein and A. Beck, German P. 566,724, 1928, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1933, 27, 2001.

compounds accompanied by the evolution of hydrogen chloride.<sup>116</sup> Simultaneously polymerized substances are formed, probably from unsaturated hydrocarbons due to elimination of hydrogen chloride from the chlorinated compounds. With ethylenic hydrocarbons apparently two hydrogen atoms are removed yielding hydrocarbons containing a triple bond. This may occur in one of two ways: either direct elimination of hydrogen as hydrogen chloride

or substitution of one hydrogen at low temperatures followed by subsequent dechlorination at higher temperatures.

Other possibilities are the formation of cyclic compounds

Asphaltic bodies are made by treating petroleum distillates with sulphur or sulphur monochloride. Thus, Hermes<sup>117</sup> heated a mixture of 11 parts of tar, 2 parts of resin and 1 part of sulphur to the melting point of sulphur and then added 11 parts of powdered lime to the brown, thickened mass. The product was a brown, opaque, resinous mass insoluble in water.

Landsberg<sup>118</sup> obtained an insoluble sulphur-containing material by the action of sulphur and sulphur monochloride on oils from the dry distillation of acid sludge.

Knight<sup>119</sup> secured an extremely hard material by heating residual hydrocarbons (asphaltum, pitch, natural bitumen) with about 1 per cent of sulphur to 204°C. Reducible metallic oxides, such as those of iron, lead or manganese were added to assist dehydrogenation and subsequent hardening. Earthy substances (aluminum silicate, talc, calcium carbonate and silica) also are incorporated. The resulting plastic may be molded into various forms. It is described as non-porous, non-adsorptive and resistant to acid and alkali corrosion. Dehydrogenation of petroleum residues and subsequent condensation of the unsaturated hydrocarbons, by heat and pressure, is recommended by Murez.<sup>120</sup>

Another procedure<sup>121</sup> comprises distilling a mixture of crude oil and calcium carbonate to a temperature of 274°C., the latter being added to neutralize any sulphuric acid formed. The residue is treated at 250°C. with sufficient sulphur to give the desired consistency. Residues from certain Rumanian oils require about 7.4 per cent of sulphur, but too much of this element adversely affects the ductility of the bitumen. Egloff<sup>122</sup> suggests heating residues from cracked distillates with 5-10 per cent of sulphur (or sulphur compounds) at 260°C. and a pressure of 50 pounds for 6 hours. Volatile compounds are continuously removed during the operation.

## RESINS FROM ACID SLUDGE AND PETROLEUM SULPHONIC ACIDS

Concentrated or fuming sulphuric acid reacts with various types of petroleum hydrocarbons to form oxygenated, condensed or sulphonated products.<sup>123</sup>

Refining of petroleum distillates with sulphuric acid yields large quantities of acid sludge, its formation being at a maximum in the drastic treatment of heavier fractions for white oils and medicinal paraffins. However, even in the less severe treatment of lubricating oils, sludges are formed which tend to become solid. Hydrocarbons responsible for such are not true unsaturates, such as are present in cracked distillates, but are more likely polynuclear naphthenes with unstable groupings or bridge structures.<sup>124</sup>

Acid sludge consists of a mixture of unchanged sulphuric acid, oil, viscous or solid oxygenated and resinous substances and sulphonic acids. Weir, Houghton and Majewski<sup>125</sup> state that flocculation and adsorption of (colloidally?) dissolved bitumens as well as sulphonation and oxidation takes place. True sulphonic acids, of which both oil- and water-soluble types exist, may be extracted from acid treated oils or sludge by caustic soda, and their sodium salts freed of sodium sulphate by further extraction with a solvent, such as ethyl or isopropyl alcohol.

Many attempts have been made to utilize acid sludge in the preparation of resins, asphalts and paint bases. Possibly because of the sulphurous nature of the initial material, no high-grade products have been produced therefrom.<sup>126</sup>

The possibility of employing acid sludge and bases in the manufacture of drying oils, varnishes and lacquers has received some attention. For example, it was proposed to make a paint oil, capable of drying to a varnish-like finish by extracting

<sup>123</sup> Although aromatic hydrocarbons form sulphonic acids almost exclusively, many of the paraffins and naphthenes undergo simultaneous oxidation and sulphonation. R. A. Worstell, *Am. Chem. J.*, 1898, 20, 664; *J.C.S.*, 1899, 76 (1), 18. G. N. Burkhardt, *J.C.S.*, 1930, 2387. C. J. Istrati and M. Michalescu, *Bull. Soc. Sci. Bucharest*, 1904, 13, 143; *Chem. Zentr.*, 1904, 2, 1447. Hydrocarbons containing a tertiary grouping are more readily sulphonated and oxidized than straight chain aliphatics and the large losses experienced in acid refining of mineral lubricating oils may be attributed partly to sulphonation and oxidation of such branched-chain compounds. B. T. Brooks, "The Non-Benzenoid Hydrocarbons," The Chemical Catalog Co., Inc., New York, 1922, 63.

Q. van Leiden Hulzebosch (British P. 8,462, 1898; *J.S.C.I.*, 1899, 18, 361) state that solidification of petroleum residues is effected by intimately rubbing together, for a prolonged time, a mixture of them and resin with slaked lime and water until a tough mass is produced which will harden on standing. This can be molded by pressure into a firm body. Asphalts in petroleum refining, note, C. B. Forward and J. M. Davidson, British P. 20,879, 1896; *J.S.C.I.*, 1899, 18, 128. J. A. Soriano (French P. 332,051, 1903; *J.S.C.I.*, 1903, 22, 1196; 1904, 23, 55) mixed a bitumen composition with an alkali earth compound to convert acid tar from petroleum into a product resembling purified soft bitumen, the tar is kneaded with an amount of iron filings or borings more than sufficient to combine with the sulphuric acid present; C. Rave, British P. 607, 1888; *J.S.C.I.*, 1889, 8, 112; W. P. Thompson, *J.S.C.I.*, 1888, 7, 303. For the production of asphalt from sludge, see M. E. Schmitz, *Bull. soc. ind. Mulhouse*, 1927, 92, 693, 695, 698; *Brit. Chem. Abs.*, B, 1927, 384, 385. Hard pitch from acid sludge: O. Diekmann, U. S. P. 1,703,615, Feb. 26, 1929; *Brit. Chem. Abs.* B, 1929, 466. Oxidizing petroleum residues, see G. H. Grey, British P. 18,302, 1898; *J.S.C.I.*, 1898, 17, 1137. A. V. Adiasewitch (*Zap. imp. russk. tech. obschch.* 29, 93; *J.S.C.I.*, 1896, 15, 346) prepared resinous material from lubricating oil residuum by blowing with "de-oxygenated" air at 150-200°C and subjecting the material to a simultaneous discharge of electricity. See also Kouindjy, *Bull. de la soc. d'encouragement pour l'industrie nationale*, 94, 1116; *J.S.C.I.*, 1896, 15, 533. C. J. Burkley (U. S. P. 1,306,520, June 10, 1919; *Chem. Abs.*, 1919, 13, 2140) subjects a mixture of gilsonite, 5 parts, and cylinder oil, 6 parts, to air blowing at 175-225°C. for about 3 hours and produces a tough plastic material with a dull luster. W. Daitz (German P. 336,603, 1918, to Harburger chem. Werke Schön & Co.; *J.S.C.I.*, 1921, 40, 651A) makes a hard asphalt from residues, obtained in treatment of mineral oils, by mixing with magnesium oxide and water (to neutralize free acid) and then blowing with air at 130-170°C. See also W. R. Wardell, U. S. P. 1,385,511, July 26, 1921, to Central Commercial Co.; *J.S.C.I.*, 1922, 41, 5A.

sludge with water, neutralizing the oily or resinous residue and removing the separated oil.<sup>127</sup> Or the neutralized residue was dissolved in a mixture of alcohol and benzene, oil of turpentine or tar oil to give a lacquer.<sup>128</sup> The latter was said to be quick drying, owing to the presumed siccative properties of the petroleum acids, and could be used on wood, metal and leather.

Bird<sup>129</sup> suggests diluting sludge with water to approximately 25 per cent concentration, warming to about 100°C., and treating with a halogenating agent, e.g., sodium chlorate. The resinous body thus formed, when hot, is a translucent mass and can be drawn into long silky threads possessing a coppery luster. On cooling it becomes friable and can be ground to a powder. The resin dissolves in alcohol and evaporation of the solvent yields reddish-brown scales similar in appearance to shellac. This substance may be employed in the manufacture of phonograph records, insulating media and as a constituent of moldings.

Preparation of resins from oil-refining sludges is described by Demann.<sup>130</sup> Three methods are advanced which consist of treatment (a) with bleaching earths, such as silica gel or fuller's earth; (b) with substances which coagulate or resinify, e.g., phenols, sodium phenolate or formaldehyde; or (c) with water and a heavy benzine, benzene, tetralin, or liquids of either a strongly aliphatic or polymethylene character. Products are separated from the acid or other associated liquids.

Substances resembling blown asphalts are obtained by the following procedure.<sup>131</sup> Approximately equal quantities of petroleum asphalt and sludge are heated to 120°C. After thorough agitation, the temperature is raised slowly to 250°C. and maintained until complete decomposition of acid compounds is effected. A mixture of petroleum residues and animal or vegetable oils may be subjected in like manner to the action of sulphuric acid at 120°. After removal of volatile components, by distillation, a plastic or elastic residuum is obtained.<sup>132</sup>

Water-soluble petroleum sulphonic acids, or "green" acids, are extracted from acid sludge with alkalis.<sup>133</sup> These substances are readily soluble in alcohols, chloroform and benzene, and less soluble in carbon tetrachloride, carbon disulphide, ether, naphtha and xylene. They appear to be monosulphonic acids having molecular weights of about 400-500. When anhydrous, the acids are dark, gummy hygroscopic materials or even solids and somewhat resinous.

Oil-soluble, or "mahogany," sulphonic acids are secured by washing acid treated and neutralized high-boiling petroleum distillates with solvents such as an aqueous solution of acetic acid or its water-soluble esters,<sup>134</sup> or with isopropyl alcohol.<sup>135</sup> Such acids are lighter in color than green acids, and are soluble in ether or chloroform but insoluble in amyl alcohol.

According to von Pilat, Sereda and Szankowski,<sup>136</sup> three classes of petroleum sulphonic acids may be distinguished by the solubility of their calcium salts:

<sup>127</sup> Millochan, U. S. P. 37,918, Mar. 17, 1863. G. W. J. Bradley (British P. 412,343, 1934, to Woodall-Duckham, Ltd.; *Chem. Abs.*, 1934, 28, 7564) suggests treating acid sludge with boiling water.

$\alpha$ -Sulphonic acids occurring principally in acid sludge, but also partly in the oil layer; the calcium salts are soluble in water or ether.

$\beta$ -Sulphonic acids; found mainly in the oil phase but also in sludge when oleum is used; the calcium salts are insoluble in water but soluble in ether.

$\gamma$ -Sulphonic acids; present only in acid sludge; the calcium salts are soluble in water but insoluble in ether.

Salts of both green acids and mahogany acids have been suggested as constituents of lubricants. Such a material to be used in the die-drawing of metals consists of sodium salts of water-soluble acids, tallow and water, the ingredients being heated to 82°C. to effect homogeneous mixing.<sup>137</sup> Alkali salts of oil-soluble acids, either alone<sup>138</sup> or emulsified with mineral oils and animal fats,<sup>139</sup> have been proposed also. Another preparation contains petroleum lubricating oil, an alkali soap of a fatty acid (e.g., sodium oleate) and an alkali metal oil-soluble sulphonate.<sup>140</sup> The latter facilitates feeding of the lubricant by a wick. A similar mixture may be employed for lubricating artificial silk during spinning.<sup>141</sup>

A flexible, transparent, gelatinous product is made by evaporation of an aqueous solution of gelatin containing a clear oil (medicinal white oil) emulsified with the aid of mahogany sulphonates.<sup>142</sup>

Heavy metal sulphonates may be used as driers, either alone or in combination with other driers.<sup>143</sup> For example, sodium salts of oil-soluble sulphonates, after extraction with 35-65 per cent aqueous alcohol, are freed of oil with 10-20 per cent of gasoline. The salts then are converted to oil-soluble lead, cobalt or manganese sulphonates, and the latter separated from insoluble material with an organic solvent, e.g., a mixture of benzene containing 75 per cent of ethyl or isopropyl alcohol. A composition of 5-25 per cent of oil-soluble calcium sulphonates, 5-25 per cent resins and 50-90 per cent of a drying oil is suggested as the film-forming constituent of varnishes.<sup>144</sup>

#### RESINS FROM CHLORINATED PETROLEUM HYDROCARBONS

Chlorination of petroleum hydrocarbons has been utilized in two distinct ways for producing synthetic resins. In some cases the chlorinated derivatives of high-boiling petroleum fractions are resins or resin substitutes. In other instances elimination of hydrogen chloride from such chlorinated material yields hydrocarbons of varying degrees of unsaturation, some of which may be polymerized to resinous substitutes or used as drying oil substitutes.

#### CHLORINATED PETROLEUM HYDROCARBONS<sup>145</sup>

Paraffin, ceresin, montan wax and petroleum oil can be chlorinated to a high degree by dissolving in carbon tetrachloride and introducing chlorine for a pro-

<sup>145</sup> A more extensive discussion of resins from chlorinated hydrocarbons is given in Chapter 56.

tracted period. If a rise in temperature occurs during the early stages of the reaction, the temperature is allowed to fall before introduction of chlorine is continued. In this way paraffin, containing 70 per cent of chlorine, furnishes a transparent solid substance. Highly chlorinated paraffin is very resistant to acids and alkalis. It is not attacked by boiling 65 per cent nitric acid, concentrated hydrochloric acid or 10 per cent aqueous caustic soda solution. Chlorinated ozokerite is scarcely effected by fuming nitric acid at 300°C. under pressure. In spite of this resistance to various reagents, chlorinated aliphatics exhibit a tendency to split off hydrogen chloride on long standing. Apparently the chlorine atoms are not bound so firmly as in chloronaphthalenes (Halowax).<sup>146</sup> The use of various chlorinated paraffins in the manufacture of chewing gum is described by Geller.<sup>147</sup>

Chlorination products of drying oils, paraffin wax, naphthalene and various other substances are employed by Blakeman<sup>148</sup> in paints. Asphaltic oils, fish oil, waxes and coal-tar, all chlorinated to a greater or lesser degree, are proposed by Ellis<sup>149</sup> as flame-proof insulators. A mixture of chlorinated asphaltum and chlorinated vegetable oils, the latter serving as a toughening agent, is used by Wickenden<sup>150</sup> in paints and varnishes. For example, petroleum pitch or asphaltum, melting at 120°C., and 10-20 per cent of cottonseed oil are treated with chlorine in carbon tetrachloride solution until absorption is complete. The solvent is removed subsequently by distillation.

#### CHLORINATION AND DECHLORINATION

Methylcyclopentane has been utilized in the preparation of resinous condensation products similar to those from cyclohexadiene.<sup>151</sup> A petroleum fraction (from Caucasian petroleum) boiling from 68-73°C. is chlorinated to yield a dichloromethylcyclopentane. The latter is dissolved in glacial acetic acid and treated with a small proportion of sulphuric acid. Elimination of hydrogen chloride and subsequent polymerization of the resulting methylcyclopentadiene probably occurs. When the dichloro derivative is dissolved in two parts of acetic acid and boiled with 20 per cent of zinc chloride, hydrogen chloride is evolved copiously and a resin precipitated.

Bielouss<sup>152</sup> and Gardner<sup>153</sup> chlorinate petroleum and then dechlorinate the product by heating to 220-240°C. to obtain a drying oil.<sup>154</sup> If the temperature during dechlorination rises above 250°C. resinous and asphaltic substances are formed. Dechlorination is accelerated by catalysts such as metallic iron, aluminum or zinc or their oxides.

Dechlorination may be effected in the presence of rosin, in which case the acidic component (rosin) is neutralized during heating.<sup>155</sup> The resulting product can be used as a paint vehicle. If a high-boiling glyceride, e.g., soya oil or hydro-

generated whale oil, be substituted for rosin and the mixture distilled under reduced pressure, then a distillate is obtained which possesses the properties of a drying oil and the residue (after cooling) is generally a hard, brittle resin.<sup>108</sup> The latter may be employed in varnishes. Unsaturated, or dechlorinated, oils can be compounded with rubber and utilized in the manufacture of molded articles or rubberized fabrics.<sup>107</sup>

Viscid resinous condensation products are made from high-molecular-weight hydrocarbons by successive halogenation and dehalogenation followed by evaporation, or from heavy petroleum oils by chlorination and subsequent treatment with Devarda's alloy.<sup>108</sup> On distillation, the resinous products give a residue of pitch which is said to be applicable as a brewer's pitch.<sup>109</sup> The distillate can be submitted again to the same treatment. Oil-like bodies, recovered from petroleum tar by distillation under reduced pressure, are converted into non-reactive resins by chlorination followed by distillation.<sup>100</sup> Extraction of the distillation residue with a selective solvent yields the purified resin.

The following procedure is suggested by Hultman<sup>101</sup> for preparing a soft, rubbery, vulcanizable material. A mineral oil boiling above 205°C. is treated at temperatures below its boiling point with a polymerizing agent, e.g., cerium oxide or dioxide. The product is cooled to about 17°C. and subjected to the action of an activated reducing gas (such as methane and carbon monoxide contacted with nickel or platinum at 205°C.) and finally to a halogenating agent, chlorine, bromine or boron fluoride. The rubbery product can be readily separated from the bulk of the oily mass.

Morrell and Egloff<sup>102</sup> described the chlorination of polymerized hydrocarbons, obtained from petroleum distillates, in the presence of phenols. The viscosity of the product is regulated by the proportion of chlorine employed.

Hydrocarbons resulting from the destructive hydrogenation of oil or coal are subjected to the action of dehydrogenating agents, e.g., chromic oxide at 500°C. The product is treated with aqueous hydrochloric acid and then passed over barium chloride. The resulting olefins are reacted with chlorine and again dechlorinated, by elimination of hydrogen chloride. Polymerization with sodium of the unsaturated hydrocarbon thus formed gives resinous or rubber-like bodies.<sup>103</sup>

#### RESINS FROM CRACKED DISTILLATES

Hydrocarbon oils, which have been subjected to thermal decomposition, or cracking, differ in important respects from corresponding fractions from crude petroleum. Unlike crude mineral oils, cracked products contain unsaturated hydrocarbons including monolefins, diolefins and olefins having aromatic substituents.<sup>104</sup> The proportion of unsaturated hydrocarbons in, for example, a cracked gasoline

<sup>104</sup> A proposed method of purifying used lubricating oils involves reducing them with a hyposulphite. A. Franke and G. Thomas, French P. 768,179, 1934; *Chem. Abs.*, 1935, 29, 594.

depends mainly upon the temperature and duration of cracking, and the pressure.<sup>166</sup> High temperature (about 600°C.) cracking at approximately atmospheric pressure, so-called vapor-phase processes, yields gasoline with a relatively large proportion of olefins. At lower temperatures and superatmospheric pressures, sometimes designated liquid-phase cracking, distillates with a smaller percentage of unsaturates are produced.

Cracked distillates, especially cracked gasoline, because of these unsaturated hydrocarbons may be regarded as a potential source of synthetic resins. Resinous or gummy substances obtained by oxidation of such hydrocarbons, particularly by exposure of cracked gasoline to air or oxygen, though as yet of no practical value are discussed because they appear to have some possibilities. Perhaps the most successful method of utilizing olefins in cracked distillates as raw materials for resins is by controlled polymerization. An example of such a procedure is the action of aluminum chloride on gasolines containing monoolefins, diolefins and aromatics. Of interest in this connection is the formation of resinous products in the large-scale refining of cracked gasoline with sulphuric acid, zinc chloride or activated earths.

**Gumming of Cracked Gasolines.** When cracked gasolines are allowed to stand in contact with air for prolonged periods of time a semi-fluid, brown, sticky mass gradually accumulates in the container. This material is designated "gum" because of its similarity in appearance and consistency to natural gums. Its formation is accelerated by bright sunlight or rise in temperature. Gum is produced also by evaporation of cracked gasolines in the presence of air.

The formation of gummy deposits, by slow oxidation of oils, was probably noted first by Schönbein.<sup>166</sup> Such resinification is described also by Hall<sup>167</sup> and by Dunstan and Pitkethly<sup>168</sup> for cracked distillates, by Nash<sup>169</sup> for oils separated from Athabaska "oil sands," by Hoffert and Claxton for crude benzol,<sup>170</sup> and by Forbes-Leslie<sup>171</sup> and Neubronner<sup>172</sup> for shale oil distillates. A study of these resins from the standpoint of petroleum refining was made by Ellis and Wells.<sup>173</sup> Procedures for removal of resin-forming hydrocarbons from petroleum distillates are discussed by Petrov,<sup>174</sup> Schwartz,<sup>175</sup> Black and Chappell,<sup>176</sup> Teplitz,<sup>177</sup> and others.<sup>178</sup>

The work of Smith and Cooke<sup>179</sup> indicated oxidation of hydrocarbons to aldehydes and polymerization of the latter to be the cause of gum- and resin-formation in cracked gasolines. Moisture and light accelerated these reactions. At first

it was thought that phenol-aldehyde resins were formed, but the absence of phenols and further investigations on the behavior of aldehydes led Smith and Cooke to the conclusion that aldehydes alone were responsible for resinification. It was noted that gum initially obtained was sticky, but on standing became harder, and on prolonged drying ultimately gave a hard, brittle resin. The latter was partly soluble in acetone, whereas soft gum was entirely soluble in that solvent. As much as 18 per cent of oxygen was present in some gums.

Brooks<sup>190</sup> studied the gum obtained by slow oxidation of cracked gasoline and found it contained a complex mixture of organic peroxides, aldehydes, ketones and acids. He also showed that aldehydes alone were not capable of forming gum under his experimental conditions. However, Wagner and Hyman<sup>191</sup> noted that a solution of crotonaldehyde in straight-run gasoline, subjected to the action of oxygen and light, yielded considerable quantities of gum similar in characteristics to that from cracked gasoline.

As a result of his work, Brooks put forward the theory that the initial step in gum-formation consisted in the development of organic peroxides, of the type

acids were regarded as decomposition and reaction products of the peroxides. In support of this view, Brooks found that a marked positive test for peroxides can be obtained in a refined cracked gasoline after exposure to air and sunlight for half an hour. Furthermore, freshly-formed gums contained a substantial proportion of explosive organic peroxides. This theory of the intermediate formation of peroxides has been substantiated by other investigators. The unsaturated compounds responsible for the production of peroxides are probably conjugated diolefins, aromatic olefins and similar reactive unsaturated hydrocarbons.<sup>192</sup>

Tauss<sup>193</sup> concluded that the color which appears when benzenes or benzols are shaken with sulphuric acid is the result of a condensation of sulphur or oxygen compounds with olefins. When exposed to air the dye, thus formed, goes over to acid resins. Carpenter<sup>194</sup> states color reversion is due to unstable resin-forming bodies, some of which are members of the cyclopentadiene family, including indene, cumarone, fulvenes, fluorene and their homologues. Hydrocarbons of these classes exhibit a strong tendency towards peroxide formation. Amend<sup>195</sup> observed the presence of a small proportion of terpenes, and related hydrocarbons, in cracked distillates. Such hydrocarbons were easily converted by oxygen into resinous or rubber-like bodies. Baxter<sup>196</sup> noted that oxygen was necessary for gum-formation in gasolines from Colorado oil shales. Reaction was more rapid in sunlight than in the dark and was accelerated also by ozone but inhibited by phenylhydrazine. Gums from shale gasoline were soluble in methyl alcohol.

Cassar<sup>197</sup> reports that simple monolefins, when added to olefin-free gasoline in

concentrations as high as 20 per cent, do not yield gum even when subjected at 100°C. to air under 100 pounds pressure. Diolefins in gasoline, however, readily form gum on evaporation of the solvent. Aliphatic or cyclic diolefins and monolefins attached to a benzene ring are considered the gum-forming constituents of gasoline by Flood, Hladky and Edgar.<sup>122</sup> Fractions of cracked distillates giving the greatest proportions of gum possessed boiling points corresponding to those of conjugated diolefins and cyclo-olefins.<sup>123</sup> The latter types of hydrocarbons may be removed by treatment of cracked distillates with sulphuric acid or maleic anhydride.<sup>120</sup>

The work of Mardles and Moss<sup>121</sup> also indicates that gumming of cracked spirits is essentially oxidation involving formation of organic peroxides. Usually on exposure of such liquids to air, there is a period of induction when the rate of gumming is small; this is followed by more rapid reaction as the products of oxidation accumulate. The rate is increased also by (1) aeration, (2) increased temperatures, (3) action of actinic light, and (4) the presence of certain sulphur and easily peroxidizable compounds. On the other hand, gumming is inhibited by addition of "anti-oxygen," e.g., phenol or thymol, by surfaces, such as soda-lime, iron or copper gauze,<sup>122</sup> and by water. A light-colored viscous gum was prepared by heating vapor-phase gasoline at 50°C. for about three weeks. Steam distillation of the gum yielded organic acids, aldehydes and other oxygenated hydrocarbons, and neutral oil. Furthermore, this gum, which also contained active oxygen, was soluble in hot water to the extent of about 30 per cent, and the remainder dissolved in dilute caustic soda solution. These results are comparable with those obtained by Brooks with a pale yellow resin which had been stored for about 6 months. This resin contained 30 per cent of material soluble in water, 30 per cent of neutral oil consisting chiefly of aldehydes and ketones, and about 40 per cent soluble in 3 per cent aqueous alkali. On distilling the gummy residue from cracked gasoline, Wagner and Hyman<sup>124</sup> observed a series of explosions and the evolution of vapors of acrolein. Similar observations on the decomposition of residues from cracked distillates were previously reported by Ellis and Wells.<sup>124</sup>

An examination of resins made from cracked gasolines under various conditions is reported by Story, Provine and Bennett.<sup>125</sup> That obtained by evaporation of the gasoline in a copper dish was a brown powder, insoluble in water and almost completely insoluble in acetone, alcohol or chloroform. It had a molecular weight of 200, began to soften at 98°C., melted at 105°C. and boiled with decomposition at 164-169°C. On heating with alcoholic potassium hydroxide, a large proportion of the material was saponified. One hundred grams of the gum, under the latter conditions, yielded only 13 g. of unsaponifiable constituents, while 55.0 g. of water-insoluble and 30.5 g. of water-soluble acids were recovered from the hydrolyzed product.

Exposure of cracked gasoline to sunlight and air at 27°C. gave a gum which was a viscous, sticky liquid, and gradually turned brown. When dried, this

<sup>120</sup> Reaction between maleic anhydride and conjugated diolefins is discussed in Chapter 40.

<sup>121</sup> E. W. J. Mardles and H. Moss, *J. Inst. Pet. Tech.*, 1929, 15, 657.

<sup>122</sup> On the other hand, the "copper-dish method" for determination of gum usually yields higher and more erratic results than methods employing other surfaces, e.g., glass or porcelain. This may be attributed possibly to the catalytic effect of copper. See, for example, V. Voorhees and J. O. Eisenger, *Oil and Gas J.*, 1928, 27 (31), 152; *Chem. Abs.*, 1929, 21, 2286. W. Littlejohn, W. H. Thomas and H. B. Thompson, *J. Inst. Pet. Tech.*, 1930, 16, 684. E. B. Hunn, H. G. M. Fischer and A. J. Blackwood, *S. A. E. Journal (Penn. Sect. Paper)*, 1930, 26, 31; *Nat. Pet. <sup>124</sup> C. R. Wagner and J. Hyman, *J. Inst. Pet. Tech.*, 1929, 15, 676.

<sup>124</sup> Carleton Ellis and A. A. Wells, *Ind. Eng. Chem.*, 1915, 7, 1029.

<sup>125</sup> L. G. Story, R. W. Provine and H. T. Bennett, *Ind. Eng. Chem.*, 1929, 21, 1079.

soft gum was converted into a material very similar to that produced by the copper dish method. The dried gum had a molecular weight of 338 and on saponification with alcoholic potassium hydroxide yielded the following substances:

	Per Cent
Unsapönifiable matter { Steam-volatile . . . . .	12 20
{ Non-volatile . . . . .	8 93
Steam-volatile acids . . . . .	6 20
Non-volatile acids { Water-insoluble . . . . .	38 24
{ Water-soluble . . . . .	33 18

All gums were the result of oxidation reactions and peroxides were present in the early stages. The chief constituents were acids which, from their physical properties and composition, appeared to be polymers of unsaturated acids. Absence of saturated fatty acids is significant. The unsapönifiable portion resembled polymerized aldehydes, ketones and oxides. Gum formed in sunlight differed from that obtained by evaporation in being more highly polymerized or condensed and also more extensively oxidized.

It is interesting to note that gums are formed by the action of phosphorus pentoxide at 30-50°C. on the unsaturated hydrocarbons in lubricating oils or kerosene.<sup>196</sup> The products are thick, sticky, reddish-brown materials and may be removed from the oil by washing with water.

Wagner and Hyman<sup>197</sup> report that on treating a gasoline, which gave a large proportion of gum on evaporation, with a concentrated solution of alcoholic potassium hydroxide a violent reaction took place accompanied by the formation of a reddish-brown resin.

#### RESINS BY POLYMERIZATION OF CRACKED DISTILLATES

An account of the polymerization of unsaturated hydrocarbons under the influence of heat, energy activation and catalysts is given in Chapter 9. Polymerization of simple monolefins does not yield resinous polymers of high molecular weight, the products being mostly oily or viscous liquids. On the other hand, controlled polymerization of conjugated diolefins and olefins of the styrene type furnishes high-molecular-weight resinous polymers. The use of particular fractions of cracked gasoline as raw materials for such resinous polymerized bodies has been suggested repeatedly.

Reference has been made (Chapter 9) to the formation of resins by the action of aluminum chloride on highly cracked gasolines containing aromatic, diolefin and olefin hydrocarbons.<sup>198</sup> Such resins are probably the result of simultaneous polymerization of monolefin and diolefin hydrocarbons and also condensation of diolefins with aromatics. The product is amber-colored, melts at 230-240°F. (ring and ball method), is soluble in practically all hydrocarbon solvents but insoluble in methyl or ethyl alcohol and acetone. It is neutral, possesses an iodine number of 130-160 and a saponification value of 5-15 (see Fig. 52). The resin dissolves readily in

linseed or tung oil and yields quick-drying varnishes. The chief advantages are stated to be fastness to light and speed of drying when incorporated with drying oils. The varnish films display a tendency to bleach.

In refining cracked gasolines with adsorbent earths, such as fuller's earth, various clays, bauxite or activated carbon, polymerization of reactive unsaturated hydrocarbons takes place on the surface of the contact material.<sup>199</sup> In one method, gasoline is vaporized and passed through the adsorbent at a temperature of about 200°C. This yields a refined gasoline and leaves gummy and resinous polymers in the adsorbent so that frequent revivification becomes necessary. Another procedure consists in conducting liquid gasoline through a bed of refining material maintained at 100°C. and redistilling the filtrate. Polymers and gums are washed out of the contact mass and recovered by evaporation of the solvent. In this manner the effectiveness of the polymerizing agent is prolonged. Vapor-phase refining of cracked gasolines is more generally utilized especially at temperatures above 200°C. and at superatmospheric pressures.<sup>200</sup> Cracked gasoline is treated also with clay at 600-650°F. and 1000 pounds pressure. The mixture is then passed to a vaporizing drum, and gasoline distilled from clay and polymers by reduction in

pressure.<sup>201</sup> In addition to the previously mentioned materials, pumice stone, Floridin and silica gel promote polymerization.<sup>202</sup> Brooks<sup>203</sup> noted pronounced ability of certain sedimentary rocks of Oklahoma to effect polymerization of hydrocarbons. Several were nearly equal to the best grades of fuller's earth.

Gray and Mandelbaum<sup>204</sup> passed the vapors of gasoline containing diolefins and other unstable hydrocarbons through an adsorbent catalyst, Floridin earth of 60-90 mesh. They found that polymerization occurred accompanied by formation of high-boiling liquids. These polymers were yellow to ruby-red or green viscous oils or resinous substances and amounted to 0.3-1.0 per cent of the distillate treated. In one instance, after separation of gasoline, the residual polymers were fractionated under 0.2 mm. pressure and yielded a fraction boiling at 300-400°F. and a semi-solid tacky residue. The physical properties of the former, which was unsaturated (iodine number of 200), corresponded with those of a lubricant. Incorporation of the thick residues with linseed or tung oil and addition of a

japan drier yields a varnish.<sup>205</sup> On the other hand, treatment of the light ends (those boiling below 113°C.) of vapor-phase-cracked gasoline with activated clay gives a pale yellow product. Distillation of the latter leaves a residual, transparent, rapidly drying oil.<sup>206</sup>

Dunham<sup>207</sup> obtained a resinous product by conducting hydrocarbon vapors, having 5-10 per cent of diolefins, through bauxite, fuller's earth, animal or vegetable charcoal or porous clay, heated to about 200°C. The resin, representing a nearly quantitative conversion of the diolefins, was molten at this temperature, flowed through the contact mass, and was withdrawn. It solidified to a brittle substance, in appearance somewhat resembling the darker varieties of colophony. It was soluble in alcohol, benzol and acetone, slightly so in ether and about 50 per cent dissolved in gasoline. The resin is suggested for varnish manufacture, for insulating compositions, and may be vulcanized with sulphur.

Refining of gasoline, naphtha, burning and lubricating oils at high temperatures with finely divided substances is described by Leslie and Barbre.<sup>208</sup> Oil is run into a digester provided with reflux, and polymerizing agents then added. The latter may be fuller's earth, kieselguhr, clay, charcoal or powdered coke mixed with an alkaline substance, e.g., calcium carbonate. Alternate refluxing and distillation is employed, some distillate being eliminated after each refluxing treatment. As the more volatile fractions are gradually distilled, the temperature of refluxing rises. Combined treatment in this fashion ultimately gives a product which, after removal of heavy oils by steam distillation, yields a residue exhibiting resinous properties.<sup>209</sup> Smith and Ziser<sup>210</sup> suggest allowing cracked distillates to age for about 2 weeks, extracting any petroleum acids formed with alkalies, and then removing resins by adsorbent earths.

Resinous polymerized hydrocarbons which remain on the contact materials can be extracted by solvents such as a mixture of alcohol and ether or liquid sulphur dioxide.<sup>211</sup> These extracted substances may be added to lubricating oils to bring the latter to a standard color.<sup>212</sup>

Morrell and Egloff<sup>213</sup> subject the resinous substances, recovered from spent adsorbents, either to the action of oxidizing agents (air, oxygen or ozone) at slightly elevated temperatures, or to the polymerizing effect of salts such as ferric, zinc or stannic chloride, or to a combined treatment of both. Hard resins can be obtained which may be employed for varnish, paint, insulating films or fillers. A modification of the above procedure consists in oxidizing in the presence of phenolic compounds.<sup>214</sup> For example, a mixture of equal parts of resinous polymers and phenols or tar acids is heated to 300°F. in a current of air, until the mixture at-

tains the desired viscosity or hardness. Action of the oxidizing agent is promoted by ultraviolet or actinic light.<sup>215</sup> An alternate procedure is chlorination of the resin phenol mixture.<sup>216</sup>

Resinous polymerized hydrocarbons are obtained by treatment of cracked distillates, particularly those containing diolefins, with hot concentrated aqueous zinc chloride,<sup>217</sup> pumice saturated with an alcoholic solution of zinc chloride,<sup>218</sup> stannous chloride<sup>219</sup> and aluminum chloride.<sup>220</sup> For example, with the last-named agent a drying-oil substitute, a mixture of polymerized olefins and diolefins, may be obtained as a by-product in the refining of highly cracked distillates.<sup>221</sup> In the case of aluminum chloride very resinous and sticky polymers often are formed which are difficult to remove from the reactor and involve loss of the metallic chloride. Double compounds of aluminum chloride and olefins (e.g.,  $\text{AlCl}_3 \cdot \text{C}_2\text{H}_4$ ) may be employed also.<sup>222</sup>

Although refining with sulphuric acid is still extensively practiced, large losses of hydrocarbons accompanied by formation of tars and resins often are experienced with highly cracked distillates.<sup>223</sup> To minimize such losses the use of dilute acid of various concentrations has been proposed.<sup>224</sup> Polymerization of the lower-boiling fractions of vapor-phase-cracked gasoline with dilute acid to give drying-oil substitutes is described by Hyman.<sup>225</sup> Amber-colored resins are reported to be obtained by treating petroleum distillates (containing a large proportion of olefins) with 90-95 per cent acid at 95-105°F., removing the acid-sludge and steam-distilling it after neutralization.<sup>226</sup> Such resins may be hardened by treatment with cresylic acid or formaldehyde in the presence of ammonia.

Attempts have been made to utilize the tars and resinous by-products of refining as raw materials for the production of asphalts. The difficulty attending such utilization appears to be the complete removal of sulphuric and sulphonic acids or sulphuric esters. Wilhelm<sup>227</sup> makes a neutral composition by the action of sulphur or hydrogen sulphide on acid tars at 130°C. The sulphuric acid present is reduced to sulphur which in turn accelerates resinification of the mass. Such bitumen is said to be adaptable for use in street paving, in the preparation of

roof boards, for the manufacture of varnish and briquette resins as well as for the generation of liquid asphalt.<sup>228</sup>

In the Hamburger process<sup>229</sup> acid sludge is heated at 80-100°C. until stratification into three layers occurs; a top layer of oil, an intermediate bituminous layer, and a bottom layer of sulphuric acid. The bituminous layer is separated and then freed of acid by heating to 150° while a stream of air or steam, preheated to 170-200°C., is passed through it. Benesch<sup>230</sup> suggests heating acid sludge only to 50°C. to effect stratification. The intermediate layer is removed, mixed with silica, sawdust or other inert material and extracted with organic solvents (ether, alcohols, esters or ketones) in a Soxhlet apparatus. Two liquid layers are obtained, of which the lower is mainly sulphuric acid and the upper consists of a solution of resin in the solvent. To remove the last traces of acid, the process can be repeated. Evaporation of the solvent yields the resin.

Pickering<sup>231</sup> makes a neutral resin from acid sludge by extraction with hot acetone, or other water-soluble organic solvent, followed by dilution of the acetone solution with water. Acetone is distilled off and aqueous sulphuric acid is withdrawn. The insoluble resinous material is washed with a dilute aqueous solution of sodium chloride or carbonate, and finally heated to 125°C. to eliminate all traces of solvents.

In another procedure the tar acids from refining cracked distillates are diluted first with water and then with aqueous alkali.<sup>232</sup> The latter is waste liquid from washing acid-refined benzines. Separation into two layers occurs. The upper oily layer is removed, neutralized and distilled with steam. The fraction boiling between 200° and 280°C. is heated with manganese or cobalt driers to give a varnish-like product. It may be polymerized also to hydrocarbons of high molecular weights. Treatment of the still residue with steam and air furnishes an asphalt-like substance (soluble in benzene) which may be used in lacquers.

Polymerization of mineral oils with sulphuric acid, in the presence of a small proportion of caoutchouc which acts as a priming agent, yields an elastic mass capable of being vulcanized.<sup>233</sup>

#### MISCELLANEOUS PROCESSES

Auer<sup>234</sup> proposed heating oils containing unsaturated hydrocarbons with acids, their salts, or organo-metallic compounds. The resulting mass afterwards may be subjected to the action of ultraviolet light. For example, mineral oil is heated to 300-350°C., under reduced pressure, with cobalt linolate and potassium thiocyanate. The resinous bodies so formed may be employed in the manufacture of varnish, rubber, soap or candles.

According to Arnot,<sup>235</sup> fluid compositions which harden on use are made by mixing a large proportion of tar and asphaltic bitumen with a cracked distillate boiling above 190°C. The unsaturated hydrocarbons in the latter resinify or polymerize with those present in tar or bitumen under the influence of atmospheric oxygen.

DeGiron<sup>230</sup> developed a process for the manufacture of rubber-like materials which consists in mixing petroleum fractions boiling at 280-370°C. (atmospheric pressure) with the aqueous portion of the fermentation products of hay or molasses. The mixture is aerated in direct sunlight for 70-80 hours. One to two per cent of a base, e.g., magnesium oxide, and 0.5-1.0 per cent of sulphur monochloride or 1-6 per cent of sulphur, are added and the mass heated to 115-120°C. If exposure of the mixture of oil and fermented liquor is continued for 90-100 hours longer, 75-85 per cent of the oil is converted into fatty acids which may be employed in the manufacture of soap.

Molding compositions for electrical insulation or as compounding ingredients in rubber goods are prepared by Winkelmann<sup>237</sup> by blowing a heated mixture of petroleum oil flux, asphalt and pine tar with air.

Tarry residues (as well as gaseous and liquid products) are obtained by the thermal decomposition at 496°C. of thioethers, mercaptans or disulphides.<sup>238</sup>

#### EFFECT OF LIGHT

The effect of light on petroleum products, especially cracked distillates or those containing olefins, appears to be that of polymerization or an acceleration of oxidation reactions, or probably a combination of both. The action of sunlight in promoting the gumming of cracked gasolines has been mentioned previously. These effects are indicated also by the work of Ostrejko<sup>240</sup> and of Carpenter<sup>240</sup> on the color changes observed during the exposure of petroleum oils to sunlight.

Mardles and Moss<sup>241</sup> increased the gum content of cracked gasoline by exposing samples in quartz tubes (half-filled) to the action of ultraviolet light. Freund<sup>242</sup> noted that resin formation increased with time of exposure. He believed that the source of such materials were complex unsaturated hydrocarbons and not paraffins, naphthenes, aromatics or simple olefins. Absorption of oxygen was considered to be of secondary importance. However, Vellinger and Radulesco<sup>243</sup> state the rate of absorption of oxygen by cracked distillates during irradiation (with mercury light) in pyrex glass vessels paralleled the amount of gum formed, some samples absorbing more than thirty volumes of the gas. Oils exhibiting the longer induction period yielded the smaller quantity of gum.

Increase in viscosity (by polymerization) is effected by treatment of oils, in either the liquid or vapor phase, with light from a mercury vapor lamp.<sup>244</sup> Ellis<sup>245</sup> deblooms lubricating oils with ultraviolet light in the presence of an inert gas, e.g., nitrogen, to prevent oxidation. In this manner the resin-forming constituents are polymerized. In the latter operation substitution of air for nitrogen results not only in the oil being debloomed but also a substantial proportion is converted to acids and esters.<sup>246</sup> Tauss<sup>247</sup> suggests, as a refining procedure, accelerating polymerization of resin-forming constituents by treating heated oil with a small proportion of oxygen. Reaction is catalyzed further by irradiation, the glow discharge or addition of alkalies or acids.

Cracked gasoline may also be purified by submitting it to a mild treatment with aluminum chloride (1 per cent at 60-70°C.). The rest of the gum-forming substances are largely removed by exposing the material for 3 hours at room temperature to high-frequency alternating current discharges. Unsaturated compounds which exhibit a knock-decreasing effect are said to be retained in the gasoline.<sup>248</sup>

## Chapter II

### Polystyrene and Related Resins

Styrene<sup>1</sup> ( $C_6H_5-CH=CH_2$ ), a colorless liquid boiling at  $143^\circ C$ ,<sup>2</sup> can be converted into a hard, colorless resin with attractive industrial and commercial possibilities. The resin, referred to here as polystyrene,<sup>3</sup> is the basis of commercial products which go under the trade names of Vietron,<sup>4</sup> Resoglaz,<sup>5</sup> and Trolitul.<sup>6</sup>

Polystyrene is one of the oldest synthetic resins, having been prepared by Simon<sup>7</sup> in 1839. Like most other resinification reactions the transformation of the liquid styrene to solid resin is one of polymerization:  $nC_6H_5 \rightarrow (C_6H_5)_n$ . Staudinger<sup>8</sup> represents the structure of polystyrene as a long chain of styrene groups formed by end-to-end combination at the olefinic double-bond, as follows:

However, it is conceivable that instead of a symmetrical arrangement a more or less random union of styrene groups might result

Pyrolytic products of polystyrene point to formula I as the correct structure of the polymer. That is, by heating polystyrene at atmospheric pressure at  $310-350^\circ C$ . for 6 hours or under high vacuum at  $290-320^\circ C$ . for 12 hours and fractionating the products, the following were identified:

Styrene

Distyrene

1,3-Diphenylpropane

<sup>1</sup> Other names for this compound are styrol, styrolene, vinylbenzene, phenylethylene and cinnamene.  
<sup>2</sup> For other recently determined physical-chemical properties see S. Sabetay, *Bull. soc. chim.*, 1929, 45, 60; *Chem. Abs.*, 1929, 23, 2427. See also A. P. Aleksandrov, *J. Tech. Phys. (U. S. S. R.)*, 1933, 3, 823; *Chem. Abs.*, 1934, 28, 3061.

<sup>3</sup> The resin has been generally called "metastyrene," but to indicate its polymeric nature it seems advisable to dispense with the prefix "meta," which really denotes position of substitution in the benzene-ring, and to call it polystyrene as suggested by Staudinger.

Tristyrene

1,3,5-Triphenylpentane

In no case were compounds isolated which would correspond to the structure II as a source.<sup>8a</sup>

Polystyrene is thus a long methylene-chain substituted alternately by phenyl groups. This conception of the molecular structure is confirmed by measurements of light-absorption<sup>9</sup> and Raman spectra<sup>10</sup> of solutions which indicate an alkylbenzene structure for the polymer. Also, theoretical considerations based on the determination of the streaming double refraction<sup>11</sup> of dilute solutions of polystyrene show, at least for the lower polymers, that the dissolved molecules are straight threads.<sup>12</sup> It has been estimated that in the more-highly polymerized forms there may be several thousand styrene units in the chain.<sup>13</sup>

The end valences may be satisfied by: (1) migration of an H-atom from one end of the chain to the other, or from one molecule to another:

(2) combination with a catalyst A-B, or solvent molecules and impurities present:

or (3) cyclization, ring formation by union of the two ends of the chain. The structure would then become a flattened ring or double chain:

The question of the nature of the end groups of the polystyrene chain is still undecided. The end carbons are not trivalent and the molecule does not appear to be cyclic. Although there is the possibility of ring formation at the ends of the chains similar to the rings shown by Bergmann<sup>14</sup> to occur in the dimerization

<sup>14</sup> E. Bergmann, *Ann.*, 1930, 480, 49; *Ber.*, 1931, 64, 1493.

of asym-diphenylethylene and  $\alpha$ -methylstyrene, Staudinger and Steinhof<sup>15</sup> consider it more likely that the molecule contains a double bond at one end, the mechanism of its formation involving the wandering of a hydrogen atom from the end of one chain to saturate the end of another as follows:

However, attempts to determine unsaturation by bromine absorption were unsuccessful, as well as reactions in which styrene was polymerized, or polystyrene was depolymerized, in the presence of various substances such as hydriodic acid, acetic acid, acetic anhydride, chloroform and piperidine which would be expected to add to double bonds. The final product in each case was a hydrocarbon and contained no detectable extraneous group.

#### POLYMERIZATION

Styrene may be polymerized in various ways. The change may be brought about simply by heating, catalysts may be added which accelerate the reaction, or it may occur in presence of other substances not catalysts. Styrene may be heated in an inert solvent, with or without a catalyst, or the solvent may be one that itself polymerizes or assists in the polymerization. Co-polymerization or heteropolymerization (see Chapter 4) may be utilized to produce special properties in the final polymerized product. Emulsions may be heated to form an artificial latex. In all cases, substances such as softeners, dyestuffs, fillers and pigments, may be added to modify the nature and appearance of the plastic.

Kronstein<sup>15a</sup> heated styrene in a sealed glass tube and observed that polymerization progressed in two stages. Thickening occurred gradually during the first stage and after a certain period gelatinization<sup>16</sup> suddenly set in. Polymerization is a continuous reaction in which the molecular weight and softening point of the polymer gradually increase. The apparent discontinuity noted by Kronstein is explained by the assumption that gelatinization occurs as soon as the softening point of the polymer is higher than the temperature at which the reaction tube is being heated.

#### CLASSIFICATION OF POLYMERS

Products of different properties are obtained by polymerization at a high temperature or at a low temperature. Also the properties are dependent upon the presence of a catalyst, the products of catalytic polymerization being comparable to those obtained at a higher temperature. Ostromislensky<sup>16a</sup> designated the products of low-temperature polymerization as alpha-metastyrol; high-temperature products, beta-metastyrol; and those obtained by use of catalysts, gamma-metastyrol.

<sup>15</sup> H. Staudinger and A. Steinhof, *Ann.*, 1935, 517, 35.

<sup>15a</sup> A. Kronstein, *Ber.*, 1903, 35, 4154.

<sup>16</sup> L. Auer considered this phenomenon analogous to the thickening of drying oils. See *Chem. Umschau*, 1926, 33, 216; *Brit. Chem. Abs.* B, 1926, 888.

<sup>16a</sup> I. Ostromislensky, U. S. P. 1,683,402, Sept. 4, 1928, to Naugatuck Chemical Co.; *Chem. Abs.*, 1928, 22, 3893.

Staudinger<sup>17</sup> adopted a different basis of classification. He found that all distinctions could be traced to differences in molecular weight; or, stated in another way, to differences in length of the chains formed by the polymerization reaction. He classified the polymers therefore as eucolloidal polystyrene (long chains of high molecular weight), and hemicolloidal polystyrene (short chains of relatively low molecular weight).<sup>18</sup>

The product of polymerization is not a single substance but a mixture of homologues of varying chain-length. Molecular weight determinations give only average molecular sizes. The mixture may be separated into fractions showing different molecular weights, whose solutions differ in viscosity,<sup>19</sup> and whose toughness and strength in massive form vary considerably. In fact all the properties of polystyrene are functions of the average molecular weight of the substance.<sup>20</sup>

### LOW-TEMPERATURE POLYMERIZATION

Polymerization occurs more slowly at low temperatures than at high, but the low-temperature product has a much higher molecular weight. Blyth and Hofmann<sup>21</sup> observed that styrene changed to polystyrene on heating at water-bath temperature for 3 days, whereas only a half hour was required at a temperature of 200°C. Ostromislensky<sup>22</sup> heated styrene in sealed tubes at a moderate temperature for a period which varied according to the temperature used. He suggested heating for 20 hours at 140°C., 18 hours at 155°, 16 hours at 165° or 10 hours at 175° to produce the resin.

Pure styrene at room temperature polymerizes extremely slowly and may be kept several years with only partial polymerization. Staudinger<sup>23</sup> separated the polymerized portion from a sample which had been standing for some time and found that the resin was much tougher than polystyrene prepared at higher temperatures, did not soften until heated above 200°C. and gave a highly viscous solution in benzene, the material swelling before it dissolved. The molecular weight was 350,000, indicating that about 3000 molecules of styrene had combined to form the average resin molecule. Solutions of polystyrene of such high molecular weight show pronounced colloidal properties. The solubility and swelling power of polystyrenes are apparently related to their molecular structure. Staudinger and Heuer<sup>24</sup> found that styrene polymerized with 1 per cent of p-divinylbenzene forms an insoluble resin. It is their belief that polymers of this type have 3-dimensional molecules, while those that swell in organic solvents have thread molecules. The p-divinylbenzene may be present as an impurity, formed when styrene is produced by the dehydrogenation of ethylbenzene containing small amounts of diethylbenzene.

### PROPERTIES OF POLYSTYRENE

Polystyrene resin obtained at a low or moderate temperature without a catalyst is water-white and transparent, remarkably tough, and shows a dull fracture when

<sup>17</sup> H. Staudinger, *Ber.*, 1929, 62, 2893; *Chem. Abs.*, 1930, 24, 1563.

<sup>18</sup> The isocolloid theory was first applied to polystyrene resins by Ostwald in 1922. See R. Houwink, *Kolloid-Z.*, 1934, 68, 371; *Chem. Abs.*, 1934, 28, 7580.

<sup>24</sup> H. Staudinger and W. Heuer, *Ber.*, 1934, 67, 1159, 1164; *Chem. Abs.*, 1934, 28, 6120. *Z. physik. Chem.*, 1935, (A) 171, 129; *Chem. Abs.*, 1935, 29, 2051. Cf. R. Signer and H. Gross, *Helv. Chim. Acta*, 1934, 17, 335; *Chem. Abs.*, 1934, 28, 4287.

broken (see Fig. 53). It can be cut into thin films and shavings but can be pulverized only with great difficulty. Average properties of the resin are: specific gravity, about 1.06; refractive index, from 1.50 to 1.75; hardness (Mohs), between 2 and 3; piercing potential, over 850 volts per mm.; and transverse tensile strength, about 6000<sup>28</sup> pounds per square inch. The resin is soluble in benzenoid hydrocarbons,<sup>29</sup> chlorinated hydrocarbons, cyclohexanone, ethyl and butyl acetate; insoluble in alcoholic solvents, glycol ethers, acetone, petroleum hydrocarbons and most acids and alkalis. The viscosity of the solutions varies with the molecular weight.

When heated, polystyrene first becomes elastic like rubber and at ordinary temperatures it may be compared with rubber that has been cooled to a very low temperature. It gives x-ray diffraction patterns, similar to those obtained with unstretched crude rubber,<sup>27</sup> characteristic of amorphous substances. Even when stretched to 400 or 500 per cent elongation the pattern is unchanged,<sup>28</sup> in contrast to rubber which when stretched shows regular crystalline interferences. In polystyrene a marked polarization may be observed.<sup>29</sup> A contrast may also

Courtesy Bakelite Corp.

FIG. 53.—Pieces of Polystyrene Resin.

be noted in the character of viscous solutions of polystyrene and rubber (or cellulose nitrate). The fundamental difference is considered to be in the shape of the particles.<sup>30</sup>

When heated to temperatures above 300°C. polystyrene is depolymerized to the monomer.<sup>31</sup> This reaction is not quantitative but is a convenient way of identifying the resin, for the styrene thus obtained may be converted into the characteristic dibromide, and it is a useful means of isolating styrene from a solution or complex mixture.<sup>32</sup> The material is heated until the polymer has formed, and this is recovered either by adding a non-solvent to precipitate it, or by distilling off all volatile liquids by means of steam. Destructive distillation of the resinous material then gives styrene. A small amount of the dimer (distyrene)<sup>33</sup> is formed simultaneously, which is removed by fractionating the distillate.

<sup>28</sup> Polystyrene sold under the name of "Victron" is stated to have a transverse tensile strength of 10,000-12,000 pounds per sq. in.

<sup>29</sup> In the determination of water in hydrocarbons, H. Broche and W. Scheer (*Brennstoff-Chem.*, 1933, 14, 408; *Brit. Chem. Abs. B*, 1934, 51) have used calcium chloride enclosed in capsules of polystyrene. When immersed in the hydrocarbon, the capsule dissolves.

<sup>33</sup> E. Erlenmeyer, *Ann.*, 1865, 135, 122. R. Fittig and H. Erdmann, *Ann.*, 1883, 216, 187. W. Königs

Polystyrene is resistant to most chemicals, even hydrofluoric acid and bromine having no effect on the solid resin. However, in solution it may be hydrogenated,<sup>34</sup> nitrated,<sup>35</sup> sulphonated<sup>36</sup> and chlorinated,<sup>37</sup> these reactions being confined to attack upon the phenyl groups.<sup>38</sup>

Laage<sup>39</sup> carried out the polymerization in the presence of a plasticizer to improve the flexibility of the product. He added 10 per cent ethylacetanilide and heated the mixture at 100°C. for 24 hours. Ostromislensky<sup>40</sup> dissolved a small amount of rubber in styrene and heated the solution at 140°C. The product had a nacreous luster similar to mother-of-pearl and was more flexible than the polystyrene made without admixture of rubber.

FIG. 54.

Polystyrene Eucolloid Prepared by H. Staudinger. Molecular Weight 440,000

Colored masses are obtained by dissolving fluorindenes or other dyestuffs in styrene and heating the solution. Addition of 0.5 per cent anthracene gives a violet fluorescence to the resin without affecting its transparency.<sup>41</sup> Amber-like bodies are formed by adding an azo-dye which decomposes during the heating to give a brown color.<sup>42</sup> Other kinds of coloring agents include colloidal metals, such as silver or gold, formed by thermal decomposition of metallic salts during the polymerization of styrene. The addition of 0.013 per cent of silver nitrate causes the resin to have a dark red color by transmitted light, and an opaque, gray shade by reflected light.<sup>43</sup> Spongy masses of low density suitable for heat-insulation are prepared by dissolution of gases (air, methyl chloride, carbon dioxide or dimethyl ether) under pressure in the molten resin and then releasing the pressure.<sup>44</sup>

Polystyrene is slightly permeable to moisture.<sup>45</sup> Tests have shown that the diffusion of water through polystyrene is twice that through hard rubber, gutta-percha or asphalt and about half that through soft vulcanized rubber. However, the amount of water actually absorbed is a small fraction of the quantity diffused.

A tough polymer is obtained by heating styrene at an upper temperature limit of approximately 175°C. The product formed at higher temperatures does not have the pronounced colloidal characteristics of the eucolloidal polystyrene thus far described (See Fig. 54). Its molecular weight is progressively lower as the polymerization temperature is raised, since heavy organic molecules are less stable at a high temperature than lighter ones.

#### HIGH-TEMPERATURE POLYMERIZATION

The polymer resulting from reaction at high temperatures (above about 175°C.), or at lower temperatures for very long periods, is brittle in contrast to the tough product formed under less drastic conditions. Ostromislensky<sup>46</sup> heated styrene for 40 hours at 140°C. to yield a resin which he called beta-metastyrol. Also, by heating styrene for 18 hours at 170°C., 12 hours at 180°C., and 2 hours at 185°C., he obtained the same type of product. It was transparent but dark in color and gave a shiny and lustrous fracture like other brittle materials. It was

FIG. 55  
Polystyrene Hemicolloid Prepared by H. Staudinger. Molecular Weight 3,000.

too brittle to be cut or planed and could be pulverized easily. Its shock-resistance was low and its transverse tensile strength only about 1000 pounds per square inch. The same properties result when the tough eucolloid is heated to a high temperature.

Polystyrene formed at high temperatures is a hemicolloid (see Fig. 55). It dissolves very readily in all solvents in which the eucolloid is soluble, yielding solutions of low viscosity. Solubility in ether distinguishes it from the low-temperature polymer, which is insoluble or only partially soluble in this solvent. (See Table 25.)

The upper temperature limit<sup>47</sup> at which polystyrene may be obtained is about 300°C. Above this point the resin is depolymerized.

#### CATALYTIC POLYMERIZATION

Polymerization of styrene in the presence of catalysts generally produces resins similar to those obtained at high temperatures. The color, however, is usually better due to the lower temperatures used. The main advantage of catalytic polymerization is the greater speed at which the resin is formed.

A great many different agents have been suggested to accelerate the resinification. Most of them fall into the classes of oxidizing agents (oxygen, peroxides, peracids, ozone and ozonides), acids, metallic halides and alkalies. Also light has a polymerizing effect.

**Oxygen Catalysts.** Oxygen was one of the earliest catalysts employed. In

<sup>46</sup> I. Ostromislensky, U. S. P. 1,683,403, Sept. 4, 1928; *Chem. Abs.*, 1928, 22, 3893. British P. 236,891, 1925; *J.S.C.I.*, 1925, 44, 771B.

<sup>47</sup> When styrene is heated at 300-340°C. under low pressure, some naphthalene is formed as well as distyrene and higher polymers, according to H. Fischer and A. Treibs, *Ann.*, 1925, 446, 241; *Chem. Abs.*, 1926, 20, 1242.

fact, when Simon<sup>48</sup> noticed the transformation from a liquid to a solid he attributed it to oxidation and called the product "oxide of styrol." The reaction was regarded as analogous to the oxidation of linseed oil. Blyth and Hofmann<sup>49</sup> showed that oxygen was not essential for they obtained the resin by heating styrene in a sealed tube. However, oxygen is usually present when the resin is formed, especially when the reaction is carried out on a large scale, as by heating the liquid under a reflux condenser or in an autoclave, since there is always some air above the liquid.

TABLE 25.—*Physical Properties of Various Polystyrenes.\**

Material	Mol. Wt.	Degree of Polymerization	Appearance of Precipitate	Melting Point in °C.	Solubility in Ether	$\eta_{sp}/c$ 20°C.
Dimer. . . . .	208	2	Fluid	Fluid	Readily soluble	0 17
Trimer. . . . .	312	3	Fluid	Fluid	Readily soluble	0 24
Hemicolloid polymerized with SnCl <sub>4</sub> . . . . .	3,000	30	Brittle white powder	105-110	Soluble	0 78
Polymerized at 150°C. under N <sub>2</sub> . . . . .	23,000	230	White powder	120-130	Partly soluble	4 2
Polymerized at 100°C. under N <sub>2</sub> . . . . .	120,000	1200	White fibers	160-180	Insoluble	22.
Polymerized at room temperature in air . . . . .	200,000	2000	White fibers	>180*	Insoluble	39
Highest fraction polymerized at room temperature under N <sub>2</sub> . . . . .	600,000	6000	White fibers	>180*	Insoluble	110

\* H. Staudinger, "Die hochmolekularen organischen Verbindungen," Verlag von Julius Springer, Berlin 1932, 186.

\* The rate of fusion was very slow, and a definite temperature could not be fixed

There is a difference between polystyrene formed in the absence of air or oxygen and that formed in its presence. Styrene polymerized in absence of air produces very clear, vitreous resins which form much more viscous solutions than those of resins formed in contact with air.<sup>50</sup> When styrene is heated in the presence of oxygen the two reactions, oxidation and polymerization, occur simultaneously. Addition of cobalt compounds,<sup>51</sup> or of iodine and iodine compounds,<sup>52</sup> accelerates oxidation. Perbenzoic acid<sup>53</sup> speeds up both reactions. Anthracene on the other hand accelerates oxidation but inhibits polymerization.

The polymerization products of styrene formed in the presence of oxygen always contain small amounts of polymeric peroxides and produce traces of benzaldehyde when the resins are depolymerized.<sup>54</sup> Stobbe<sup>55</sup> found that styrene which had been exposed to light in the presence of oxygen gave benzaldehyde and formaldehyde as well as the polymer. Polymerization occurs more rapidly in oxygen than

When styrene is oxidized by perbenzoic acid at a low temperature a good yield of styrene oxide is obtained according to H. Hibbert and C. P. Burt, *J.A.C.S.*, 1925, 47, 2243. See also "Styrene Oxide," in "Organic Syntheses," John Wiley & Sons, New York, 1928, VIII, 102.

<sup>54</sup> H. Staudinger and L. Lautenschläger, *Ann.*, 1931, 488, 1, *Brit. Chem. Abs. A.*, 1931, 1031.

<sup>55</sup> H. Stobbe, *J. prakt. Chem.*, 1914, 90, 551; *Chem. Abs.*, 1915, 9, 1174.

in an atmosphere of carbon dioxide. The addition of peroxides increases the rate of reaction but the effect is not as great as that of oxygen. It is concluded that an initial autoxidation product of styrene, a moloxide, is the actual catalyst when using oxygen.<sup>56</sup> Stobbe and Posnjak<sup>57</sup> observed that styrene that had stood for two weeks was more easily polymerized than freshly distilled material, probably because of autoxidation.

Ostromislensky,<sup>58</sup> by adding 1 per cent of benzoyl peroxide to styrene and heating the solution to 175°C. for an hour, obtained a brittle resin which he called  $\gamma$ -metastyrol to distinguish it from the polymers formed without a catalyst. Lawson<sup>59</sup> used benzoyl peroxide<sup>60</sup> with a solvent. Hydrogen peroxide<sup>61</sup> also has been recommended for use in emulsions. Other peroxides suggested include those of asym-diphenylethylene, cyclohexene, phellandrene<sup>62</sup> and triphenylmethyl.<sup>63</sup> Natelson<sup>64</sup> used benzoyl hydrogen peroxide, prepared in a nascent condition from benzaldehyde and an equivalent amount of oxygen. A 45 per cent solution of styrene in ethylbenzene was completely polymerized in 12 hours at 175°C. with 2 per cent of this catalyst. Barrett<sup>65</sup> obtained a product of low viscosity by heating styrene (or a vinyl ester) with benzoyl peroxide and rosin or a rosin ester at 110°C. and 500 lbs. pressure in a solvent naphtha solution.

Houtz and Adkins<sup>66</sup> studied polymerization in presence of the ozonides of a mixture of the two octylenes known as diisobutylene. A small quantity was sufficient to cause solidification of styrene in the course of a week at room temperature. Lawson<sup>67</sup> heated styrene in solvents which had previously been treated with ozone.

**Photocatalysis.** Ordinary light accelerates the polymerization of styrene. Blyth and Hofmann<sup>68</sup> found that exposure of the liquid to light in glass tubes caused thickening. Lemoine<sup>69</sup> noticed that a sample, which was probably impure, polymerized slowly in the dark. Ultraviolet light<sup>70</sup> is very effective. Taylor and Vernon<sup>71</sup> employed light from a mercury arc and noted that the process has certain characteristics of a chain reaction.<sup>72</sup> One molecule may be activated by absorption of light and react with a second molecule. The new double-molecule, which has an excess of energy, reacts with a third and so on down the line until the initially acquired energy has been dissipated.<sup>73</sup>

<sup>56</sup> H. Staudinger and L. Lautenschlager, *loc. cit.* R. C. Houtz and H. Adkins (*J. A. C. S.*, 1933, 55, 1609), contrary to the conclusions of Staudinger and Lautenschlager, have indicated that peroxides and ozonides are much more active than oxygen as polymerization catalysts. <sup>71</sup> H. S. Taylor and A. A. Vernon, *J. A. C. S.*, 1931, 53, 2527.

<sup>72</sup> Other polymerization reactions have been known to involve a chain mechanism. See, for example, J. B. Couant and C. O. Tongberg, *J. A. C. S.*, 1930, 52, 1659. H. W. Starkweather and G. B. Taylor, *ibid.*, 4708.

<sup>73</sup> H. Stobbe (*Ber.*, 1914, 47, 2701) considered the polymerization of styrene by light to be reversible. He noticed that a solution of polystyrene, after exposure to ultraviolet light, decolorized permanganate, presumably by depolymerization to form styrene. A polystyrene solution which had been kept in the dark did not decolorize permanganate.

In the presence of carbonyl compounds, styrene is readily polymerized in glass (in a few hours with benzophenone and benzanthrone under a 500-watt lamp at 60-70°C.). Apparently traces of activated oxygen play a role in initiating the chain reaction. Antioxidants inhibit the reaction.<sup>74</sup> Exposure to a concentrated electromagnetic field is said to stimulate polymerization of styrene.<sup>75</sup>

**Acid Catalysts.** Acids act as polymerization catalysts. Concentrated sulphuric acid<sup>76</sup> has a very vigorous action. Chromic acid causes rapid formation of a dark brown mass. Lespieau and Deluchat<sup>77</sup> prepared p-divinylbenzene and reported that it polymerized very rapidly to an amorphous powder insoluble in ordinary solvents. Sabetay<sup>78</sup> prepared the same compound avoiding all traces of acid, and found it to be much more stable.<sup>79</sup>

Unless present in very small amounts, acids usually impart a dark color to the resin. However, using about 0.5 per cent hydrochloric acid does not unduly affect the color and a product giving a solution of low viscosity is obtained. The reaction may be carried out at 150°C.<sup>80</sup> Fredenhagen<sup>81</sup> recommended hydrofluoric acid as a catalyst.

Stannic chloride is very active and causes polymerization even at low temperatures. When 3 per cent of this reagent is added to styrene at -3°C., reaction sets in at once and the temperature rises to 80°C. An orange-colored product is formed which is probably a complex containing the catalyst in combination. The color disappears on addition of alcohol.<sup>82</sup> Aluminum chloride,<sup>83</sup> as well as other metallic halides,<sup>84</sup> and phenyldiazonium fluoborate<sup>85</sup> are also active catalysts.

Addition of iodine in solid form<sup>86</sup> causes polymerization but using a solution of iodine<sup>87</sup> largely inhibits this action on account of the formation of iodine compounds. Iodine influences the autoxidation in contact with air.<sup>88</sup> Bromine water causes partial polymerization.<sup>89</sup>

Mercaptans<sup>90</sup> act as resin-forming catalysts especially in the presence of oxygen, a fact which has a bearing on the use of such materials as stench-producers in city gas that contains styrene. Sulphur dioxide<sup>91</sup> in the presence of oxygen or peroxides also has a positive effect on olefins in general, but not as pronounced as mercaptans. The action is explained as the result of the catalytic effect of sulphur trioxide, the latter being formed through oxidation of sulphur dioxide by the peroxides.

**Alkaline Catalysts.** Metallic sodium reacts very slightly with styrene. First a small amount of an orange-colored compound is formed and then polymeriza-

tion occurs.<sup>92</sup> Matthews<sup>93</sup> produced a tough resin by allowing styrene to stand in contact with metallic sodium for some time. A solution of sodium in liquid ammonia converted styrene partly to ethylbenzene and partly to resin.<sup>94</sup> Sodium malonic ester<sup>95</sup> causes partial resinification. When styrene is heated in a sealed tube at 100-120°C. with an aqueous solution of sodium bisulphite the polymer is formed together with sodium phenylethylsulphonate.<sup>96</sup> Alkali hydroxides, salts, organic bases or water added to an ethylbenzene solution cause resinification after prolonged heating under a reflux condenser.<sup>97</sup>

Carbonyls of the heavy metals<sup>98</sup> and lead tetraethyl<sup>99</sup> also have been suggested as catalysts.

**Negative Catalysts.** The main substances which have been found to inhibit the polymerization of styrene are sulphur,<sup>100</sup> benzoquinone,<sup>101</sup> trinitrobenzene,<sup>102</sup> anthracene,<sup>103</sup> and phenols such as hydroquinone,<sup>104</sup> cresol and pyrogallol.<sup>105</sup> Inhibitors are useful when it is desired to store styrene for long periods or to distil it. They also prevent the formation of resin from industrial gases containing styrene and other polymerizable hydrocarbons.

### POLYMERIZATION IN SOLUTION

When styrene is dissolved in a solvent and heated, a solution of polystyrene is obtained. If the liquid is a non-solvent for the polymer, the resin precipitates as formed. Berthelot<sup>106</sup> heated styrene and toluene in a sealed tube at 200°C. and obtained a solution of resin. One process of making styrene involves the thermal decomposition of ethylbenzene to give a mixture of styrene and unchanged hydrocarbon.<sup>107</sup> Ostromislensky and Gibbons<sup>108</sup> heated such a solution containing about 40 per cent styrene in the presence of air and obtained a solution of polystyrene which could be used as a lacquer or as an impregnating agent. The resin may be recovered by distilling off the solvent. Steam distillation or heating in a vacuum oven has also been used to free the resin of solvent. In a procedure involving polymerization in solution, Johnston and Keen<sup>109</sup> utilized a combination of spray-drying and steam distillation, atomizing a hot solution containing polystyrene by means of steam at high pressure.

Any soluble polymerization catalyst may be added to a solution of styrene. Lawson and Sandborn<sup>110</sup> used benzoyl peroxide. Heating 3900 grams of a 21.7 per cent solution of styrene in ethylbenzene containing 8 g. of benzoyl peroxide for 5 hours at 115-120°C. resulted in polymerizing 56 per cent of the styrene. A solution containing a catalyst is best handled by first heating a small portion until the exothermic reaction ceases and then adding the remainder of the solution gradually. A special apparatus<sup>111</sup> for this kind of work consists of a lower vessel containing the solution and an upper compensating chamber into which the liquid distills when the reaction starts and from which it returns gradually after cessation of the initial reaction.

Smith<sup>112</sup> added a small amount of an alkali hydroxide, an organic base or water to an ethylbenzene solution of styrene. Heating under reflux for 72 hours gave a tough, nonfriable resin.

In order to accelerate subsequent polymerization under heat and pressure, Lawson<sup>113</sup> subjected a solution of styrene to ozone treatment for a period of 5 hours. This procedure may become a continuous process<sup>114</sup> for the preparation of polystyrene by passing the ozone-treated solution, or any solution containing a catalyst such as benzoyl peroxide, slowly under pressure through a lead-lined tube heated at about 117°C. Passage of a 45 per cent solution in ethylbenzene (to which 3 per cent of benzoyl peroxide had been added) under a pressure of 200 pounds per square inch, and at a flow-rate of 200 cc. per hour, resulted in polymerization of 65 per cent of the styrene.<sup>115</sup>

Vinylnaphthalene<sup>116</sup> also may be polymerized to a resin. This may be done by heating the compound at 300°C., or by dissolving it in a solvent and heating at a lower temperature in presence of a catalyst. The polymer is light colored and suitable for lacquers or molding compositions. Furylethylene,<sup>117</sup> another compound related to styrene, when heated for 6 hours under pressure at 180°C. with 1 per cent of benzoyl peroxide, yields a light red syrup soluble in toluene. The polymerization can be carried out in solution and a lacquer obtained directly. Five per cent of blown linseed oil may be added as a catalyst. Polyfurylethylene forms films which dry tack-free in 8 hours and hard in 24 hours. Unlike polystyrene, it is compatible with nitrocellulose. The resinification of furylethylene is very sensitive to antioxidants, phenols (hydroquinone in particular) largely inhibiting the reaction.<sup>118</sup> Furylbromoethylene resinifies quite easily, and when exposed in a thick layer to air it changes to a solid.<sup>119</sup>

#### COMPLEXES BY CO-POLYMERIZATION

A mixture of two or more polymerizable substances, when subjected to appropriate conditions, may form a complex resin having properties different from a

simple mixture of the two polymers. A mixed-chain polymeric molecule is formed and the reaction is designated co-polymerization. The type and proportions of the different materials may be varied in any way desired, so that the number of possible co-polymers is very large. Styrene may be polymerized in the presence of vinyl chloride,<sup>120</sup> vinyl ethers and esters,<sup>121</sup> acrylic esters, acrylonitrile<sup>122</sup> and acrylyl chloride,<sup>123</sup> 2-chloro-1,3-butadiene,<sup>124</sup> unsaturated ketones<sup>125</sup> or unsaturated  $\alpha$ ,  $\beta$ -dicarboxylic acids<sup>126</sup> to yield resins. In the case of ketones, the resin formed is less brittle than the styrene resin and more soluble in benzene than a resin from the corresponding ketone alone.<sup>127</sup>

#### COMPLEXES BY HETEROPOLYMERIZATION

When a complex is formed from a mixture containing one polymerizable substance, such as styrene, and another that is not ordinarily capable by itself of polymerizing, such as maleic anhydride or cyclohexanol, the reaction is one of heteropolymerization.<sup>128</sup> Voss and Dickhauser,<sup>129</sup> by heating a mixture of 120 parts maleic anhydride and 105 parts styrene on a water bath, obtained an exothermic reaction which yielded a hard, homogeneous mass. The product from this reaction has properties different from polystyrene: it is insoluble in benzene but soluble in acetone and aqueous alkalis. The properties may be varied by changing the proportions of reactants. The constitution of the resin<sup>130</sup> may be represented as a long chain or ring of alternate maleic anhydride and styrene groups.

A solution of this heteropolymer in aqueous ammonia is recommended as a textile dressing. Fabrics are impregnated with the solution, and dried in an oven in order to eliminate the ammonia and to render the resin resistant to washing and soaping.<sup>131</sup> Color lakes for varnishes are improved as regards freedom from bronze luster when precipitated in the presence of an aqueous solution of alkali salts of styrene-maleic acid.<sup>132</sup>

Styrene-maleic anhydride may be converted into esters, salts or amides by reac-

tions affecting the carboxyl-groups of the polymer. These may be of value as germicides or antiparasitic adhesive layers and also in dyeing.<sup>133</sup> Polystyrene can also be used as a binding agent in color printing.<sup>134</sup>

Treatment with glycerol gives an ester which is insoluble in alkalis. The glyceride may also be formed by heating a mixture of maleic anhydride, styrene and glycerol in an autoclave.<sup>135</sup> Wagner-Jauregg<sup>136</sup> found that styrene and dimethyl maleate reacted to form a white, amorphous powder. Polymers of styrene, vinyl ethers and ketones condensed with aldehydes have been suggested for insulators.<sup>137</sup>

Cyclohexanol is not a solvent for polystyrene.<sup>138</sup> When a solution of styrene in cyclohexanol is heated in absence of a catalyst a turbid product resembling paraffin wax results.<sup>139</sup> Clear, colorless masses suitable for molding are obtained by including acetic anhydride or a plasticizer such as camphor or ethylacetanilide in the composition. Styrene polymerized with 5-10 per cent of a chlorobiphenyl yields a harder, less inflammable and more easily molded resin.<sup>140</sup>

### POLYMERIZATION OF EMULSIONS

When styrene is emulsified with water and heated, a latex is formed. This method of forming the resin has certain advantages. The reaction may be carried out at relatively low temperatures and the product is easily purified and very light in color.

Styrene forms a fairly stable emulsion when shaken with water containing a small amount of ammonium oleate. Heating this emulsion at 140°C. under pressure for 24 hours forms a latex which may be coagulated in the same way as rubber latex. Addition of methanol causes the polystyrene to separate in a finely divided form which is easy to wash and dry.<sup>141</sup> Styrene also may be emulsified by means of saponin, sulphonates or albuminous substances. Heating an emulsion made with milk for 10 days at 60°C. causes transformation of the styrene.<sup>142</sup> Latex formation is accelerated by addition of hydrogen peroxide.<sup>143</sup> Prior to coagulation by precipitating agents, all volatile impurities may be removed by passing steam or inert gases through the dispersion.<sup>143</sup> In this way a colorless polymer is obtained.

Co-polymerization may also be carried out with the reactants in an emulsified condition. Butadiene or isoprene and styrene form a co-polymer which is rubber-like.<sup>144</sup> For example, 2 parts of butadiene and 1 part of styrene emulsified with sodium stearate are maintained at 60°C. for several days to yield a latex which is then coagulated and the product milled with carbon black. Vulcanization of the composition gives a pliable rubber. Diethylaminoethyloleamide hydrochloride

<sup>145</sup> E. Tschunkur and W. Bock, U. S. P. 1,938,731, Dec. 12, 1933, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1934, 28, 1574. German P. 532,456, 1929; *Chem. Abs.*, 1932, 26, 337. British P. 339,255, 1929; *Chem. Abs.*, 1931, 25, 2598. French P. 699,154, 1930; *Chem. Abs.*, 1931, 25, 3521.

is recommended as an emulsifying agent. Divinylbenzene or  $\alpha$ -methylstyrene<sup>141</sup> may be substituted for styrene; or vinylnaphthalene<sup>142</sup> may be used. If the polymerization is stopped when about 20 per cent of the diolefin is unconverted the product has maximum solubility in benzene, but if the process is carried to completion poor solubility results.<sup>147</sup> The addition of a chlorine compound, such as carbon tetrachloride, ethylene dichloride, hexachloroethane or sodium trichloroacetate, to the emulsified mixture of styrene and diolefin causes an increased yield and a more plastic product.<sup>148</sup>

Ethyl acrylate (see Chapter 53) and styrene may be emulsified by means of sodium isopropyl-naphthalenesulphonate, and the emulsion on the addition of hydrogen peroxide and heating at 70-90°C. yields a co-polymer which may be formed into rubber-like threads and films.<sup>149</sup> Threads of artificial silk are produced by spinning a solution of a resin into a coagulating bath to produce a strongly swollen thread which is then stretched. Solutions of polymers of styrene, vinyl alcohol, vinyl acetate, vinyl chloroacetate, vinylamine or vinyl methyl ketone can be thus used; or, heteropolymers of these with maleic anhydride.<sup>150</sup>

### POLYMERIZATION UNDER PRESSURE

The velocity of polymerization of styrene increases with increasing pressures, and at high pressures, a lower temperature will bring about resinification.<sup>151</sup> Pressures as high as 12,000 atmospheres have been suggested, using a pressure vessel consisting of a block of chrome-vanadium steel 6 inches in diameter with a 1-inch hole drilled in it.<sup>152</sup>

### POLYSTYRENE COATINGS

On account of its solubility in cheap hydrocarbon solvents,<sup>153</sup> its toughness and light color, polystyrene offers excellent possibilities as a film-forming material.<sup>154</sup> Suggested uses to which the coatings are adapted are as clear metal lacquers and as bases for white or pale-colored enamels which do not darken in the light. The lacquers are quick-drying and even when baked for a long time the films do not become insoluble. They are resistant to water, sea water, and moderately strong acids and alkalis, but are not quite as tough as nitrocellulose films.

Exposure tests of polystyrene coatings show that plasticizers are advisable. Photomicrographs after 60 days of exposure of a coating formed from a 33 per cent solution of polystyrene in toluol showed fine cracks. A similar composition to which had been added 5 per cent of diphenyl phthalate gave high gloss and no

<sup>154</sup> A lacquer composed of polystyrene dissolved in a hydrocarbon solvent was proposed by E. Haslinger, Swiss P. 155,462, 1931; *Chem. Abs.*, 1933, 27, 1218.

checking, indicating the superiority of the plasticized film.<sup>155</sup> Some of the softer Aroclors<sup>156</sup> are suitable plasticizers. Dibutyl phthalate, triphenyl phosphate and tricresyl phosphate decrease the water-resistance of polystyrene in the order named but give clear films. Resin oils have also been suggested for this purpose.<sup>157</sup> Jaeger recommended esters of keto-aromatic acids such as methyl benzoylbenzoate,<sup>158</sup> soft substances such as phthalide-phthalic-glyceride,<sup>159</sup> or hexahydro-phthalide and substituted phthalides as plasticizers.<sup>160</sup> About 1 per cent of di-*o*-tolylguanidine added to polystyrene solutions acts as a protective agent to prevent checking of coatings.<sup>161</sup>

A difficulty encountered when using a solution of polystyrene as a spraying lacquer is cobweb formation. This is the tendency of a solution to come from the spray-gun in the form of long thread-like filaments. It generally occurs when the solution is too viscous or if the air-pressure is too low, and can usually be corrected by thinning the solution or adding other resins and plasticizers. Lawson and Sandborn<sup>162</sup> stated that the product obtained by polymerizing styrene in a solvent and in the presence of a catalyst forms lacquers which do not cobweb. Ethylbenzene is a suitable solvent for use during the resinification, and benzoyl peroxide, the best catalyst. Styrene is heated in the solution at a temperature of 115°C. until polymerized. A lacquer which does not cobweb is made from 175 parts of polystyrene thus prepared, 50 parts tricresyl phosphate and 500 parts solvent consisting of 15 per cent benzene, 45 per cent toluene and 40 per cent xylene.

When polystyrene is dissolved in carbon tetrachloride and chlorine passed through the solution in the presence of ferric or aluminum chloride at ordinary temperatures and in the dark, a chlorinated substance capable of being sprayed is obtained.<sup>163</sup> Resins having the highest chlorine content show the lowest viscosity and highest melting point.<sup>164</sup>

Lawson<sup>165</sup> used polystyrene plasticized by means of tricresyl phosphate, dibutyl phthalate, glycerol dibenzyl ether, butyl stearate or dixylylethane as a coating for glass, wood<sup>166</sup> or metal. Such a lacquer is composed of a mixture of polystyrene 17.8 parts by weight, dibutyl phthalate 4.5 (or tricresyl phosphate 3.6), ethyl acetate 20, toluol 30, xylol 20 and butyl acetate 30.<sup>167</sup> This lacquer is suitable for waterproofing shotgun shells.<sup>168</sup> Lacquers containing polystyrene plasticized with 50 per cent of diphenyl phthalate have been recommended as clear top varnishes on lithographed metal advertising signs to prevent chalking and fading of certain colors,<sup>169</sup> or as vehicles for luminous pigments.<sup>170</sup> A film of polystyrene applied to

hardened synthetic resins serves as an intermediate layer for metallic coatings.<sup>171</sup> Plasticized with aryl phosphates or phthalic esters, polystyrene can be used for impregnating fabrics,<sup>172</sup> or for waterproofing articles made of cellulose esters.<sup>173</sup> Phthalide and its derivatives serve as plasticizers for styrene resin.<sup>174</sup> Solutions of polystyrene or hydrogenated polystyrene may be used to stiffen textile fabrics, felt, straw or asbestos fibers and render them less liable to spot with water.<sup>175</sup> Cloth impregnated with a solution of polystyrene or other vinyl resin is also satisfactory for containers.<sup>176</sup> Electrical conductors can be provided with inorganic insulation by applying a coating of lead borate and over this a thin film of an alkyd resin or polystyrene. The resin film permits the conductor to be wound into coils<sup>176a</sup> and is subsequently volatilized by heating for 2 hours at 380-400°C.

In making surfaces for recording sound, metal or paper can be coated with a solution of polystyrene in monomeric styrene. After the coating is applied polymerization is completed by heating at 60°C. using benzoyl peroxide as catalyst. Hardness and elasticity are altered by incorporating paraffin.<sup>177</sup>

Polystyrene is not compatible with cellulose esters or ethers, polyvinyl acetate or Amberols, giving neither clear solutions nor clear films with these materials. However, polymerization of styrene in the presence of cellulose derivatives in solution yields a homogeneous resin suitable for coating.<sup>178</sup> Cellulose ester products, such as fountain-pens or screw caps, are coated with a film of polystyrene or its homologues to make them resistant to water, acids and alkalis.<sup>179</sup> Polystyrene is compatible with Aroclors, Cumar, ester gum and some other resins. Lacquers may be prepared by mixing solutions of polystyrene with solutions of rosin, dammar, linseed-phthalic-glyceride or methyl tetrahydroabietate.<sup>180</sup> These resins increase the adhesion.

The adhesion of coatings of polystyrene is also improved by the addition of 10-25 per cent of cumarone resin. If a chlorinated resin, such as an Aroclor, is used to the extent of about 40 per cent with polystyrene, a notably fire-resistant coating results. One composition containing polystyrene, cumarone resin and tricresyl phosphate has been used advantageously in the finishing of terrazzo floors.<sup>181</sup> Disadvantages of the use of a volatile solvent are avoided by coating or impregnating articles with monomeric styrene or a solution of polystyrene in styrene, followed by heat-treatment.<sup>182</sup> A varnish containing polystyrene, Cumar and a softener gives a film with little tendency to check.<sup>183</sup>

Walsh and Caprio<sup>184</sup> used styrene and other vinyl compounds in cellulose ester plastics. They prepared solutions containing styrene in an unpolymerized, partially polymerized<sup>185</sup> and highly polymerized form<sup>186</sup> to which were added cellulose

esters, plasticizers and other resins. When using unpolymerized styrene a catalyst such as benzoyl peroxide is introduced and the solution subjected to light and heat. The solutions are used as lacquers or the solvent is evaporated and the plastic worked up into shaped articles.<sup>107</sup> A composition consisting of 1 part cellulose acetate or butyrate, 2 parts polystyrene, 1 part p-toluenesulphonamide, 3 parts kieselguhr and 1 part chlorobenzene, homogenized in a kneading apparatus at 110-120°C., can be made into oilcloth by rolling on to a cloth web.<sup>108</sup>

Polystyrene is insoluble in drying oils but this is not true of the polymer from divinylbenzene. Dykstra<sup>109</sup> suggested a varnish which contains polymerized divinylbenzene, raw tung or linseed oil and cobalt linoleate in a solvent. A coating forms flexible films when dry. Vinylacetylene, vinylanthracene and butadiene hydrocarbons have also been recommended for use in lacquers by polymerizing them in the presence of esters of drying oil acids.<sup>100</sup>

Another suggested use for polystyrene in solution is in lubricating oils.<sup>101</sup> It is reported to improve the lubricating properties of the oil and increase the viscosity.<sup>102</sup> Alternatively, styrene may be added to the oil and polymerized in solution by heating. Hydrogenation renders the polymer more resistant to heat.<sup>103</sup> Solid lubricating greases are also said to be improved by addition of a small amount of polymerized styrene, hexene or turpentine, or hydrogenated rubber.<sup>104</sup>

### MOLDED PRODUCTS

Polystyrene may be readily molded under heat and pressure, preferably at a high temperature as this appears to eliminate internal strains and renders the article less likely to crack on aging.<sup>105</sup> A temperature of 150-190°C. and a pressure of 1000 pounds per square inch are recommended. Curing does not occur and the molded pieces are permanently thermoplastic and soluble. Moldings have remarkably high shock-resistance and are stronger than phenol resins. Their insulating power is highest of any available synthetic resin, higher even than shellac. A particular advantage of polystyrene is the low shrinkage that occurs on cooling; a commercial product has a shrinkage of 0.002 inches per linear inch of molding. These qualities are suggestive of the possible fields for utilization of the plastic.<sup>106</sup>

Strips and bars may be formed by extrusion under pressure of the heat-softened resin through an orifice of suitable size. By passing a wire through the extrusion apparatus, a tubular coating is formed on the surface of the metal (see Fig. 56). This device may be applied to the manufacture of insulated cables.<sup>107</sup> A related process<sup>108</sup> serves for the production of threads or films. In this case the addition of solvents and plasticizers to the polystyrene is recommended.

<sup>108</sup> British P. 419,826, 1934, to I. G. Farbenind. A.-G.; *Brit. Chem. Abs. B.*, 1935, 111.

Small objects are readily formed by injection molding,<sup>100</sup> the plastic being particularly adapted for this method.<sup>200</sup> The resin is heated until plastic and is then forced into a mold where it cools and hardens.<sup>201</sup> Threads, ribbons and sheets can be made by drawing polystyrene at a high temperature.<sup>202</sup>

An advantage of polystyrene as a molding material is that, like shellac, there is no waste in the process. Scraps and broken pieces may be reground and used over again. Clear masses may be formed from small pieces of unfilled material and from those containing bubbles, by adding 5 to 20 per cent of styrene and heating the mixture under a reflux condenser for 3 to 8 hours. Also small pieces may be cemented together. In working up scraps and shavings containing fillers, a fairly

FIG. 56.—Extrusion Apparatus for Coating Wire with Polystyrene Resins. (E. Studt and U. Meyer.)

dilute solution in styrene may be prepared and the insoluble matter allowed to settle.<sup>203</sup>

Posner formed objects by spraying concentrated solutions of polyvinyl compounds into molds.<sup>204</sup> Dentures are made which contain a very tough polymer from which all unpolymerized styrene has been removed, together with fillers and plasticizers.<sup>205</sup> Another type of molding is made by impregnating fibrous material with an aqueous dispersion of polystyrene.<sup>206</sup> The pulp is allowed to dry and is then pressed into the desired shape. Powdered material such as zinc oxide or finely divided asbestos<sup>207</sup> may be made into a paste with partially polymerized styrene and heated to complete the reaction before pressing. The co-polymers of

styrene and acrylic esters, vinyl esters and vinyl ketones may be worked in the same manner as that used for the manufacture of celluloid.<sup>200</sup> Hofmann<sup>200</sup> uses co-polymers of various vinyl compounds, combined with fillers and plasticizers, to make sound records.

On account of its high dielectric constant,<sup>210</sup> polystyrene is valuable in electrical insulators and condensers.<sup>211</sup> A sheath of polymerized styrene air-spaced from the conductor has been proposed.<sup>212</sup> Field, Hugh and Parsons<sup>213</sup> prepared a dielectric composed of purified rubber mixed with 40 to 80 per cent of polystyrene and up to 20 per cent of wax. Rubber compounded with polystyrene, gutta-percha and small amounts of water-resistant waxes has been similarly used.<sup>214</sup> Chlorinated naphthalene with about 1 per cent of polystyrene or rubber has also been suggested as an insulating composition.<sup>215</sup> Other material suitable for insulation of submarine cables contains the product of the co-polymerization of styrene and butadiene, dimethylbutadiene or 2-methyl-2,4-dimethylpentadiene.<sup>216</sup> Another type of cable insulation is made by heating a mixture of styrene, dimethylbutadiene and about 15 per cent of wax in an autoclave;<sup>217</sup> also by mixing polystyrene with plasticizers such as tritolyl and triphenyl phosphate, cresol or diphenylpropane.<sup>218</sup> Marble coated with polystyrene has been found suitable for radio insulation.<sup>219</sup>

Benner and Porter<sup>220</sup> proposed polystyrene as a bonding agent for abrasives. Compositions of phenol-aldehyde resin and polystyrene or shellac have also been suggested.<sup>221</sup> Grinding wheels<sup>222</sup> may be built up of segmental blocks united with a cement composed of polystyrene, plaster of Paris and a solvent. Hadnagy and Brouillard<sup>223</sup> made abrasive paper and cloth by bonding the grains of abrasive material with an adhesive containing polystyrol, used either in molten form or in solution.

#### LAMINATED GLASS

Moss<sup>224</sup> used polystyrene and other polymerized vinyl compounds as adhesives for sheets of glass and cellulose esters in safety glass. The product of the reaction between maleic anhydride and castor oil or 1,3-butylene glycol may be mixed with

polystyrene to improve its adhesion.<sup>226</sup> Polymerized vinyl compounds also may be blended with the nitrocellulose layer of safety glass and tend to lessen the yellowing effect of light.<sup>226</sup>

Transparent layers for use as glass substitutes are made by blocking compositions containing plasticizers and fire retardants and cutting into sheets.<sup>227</sup> Hopkinson<sup>228</sup> suggested a shatter-proof, glass-like product composed of alternate layers of tough polystyrene and the hard, brittle polymer. Styrene polymerized in the presence of sulphur, sulphur chloride or chlorinated hydrocarbons has been recommended for lenses, prisms and other optical elements, also as a cement for these articles.<sup>229</sup>

#### PRODUCTION OF STYRENE

More extended use of polystyrene demands a cheaper source of styrene. So far, no process appears to have been developed which puts the price on a par with that of other leading synthetic resins. Styrene has been made in a number of ways including the pyrolysis of various hydrocarbons, elimination of hydrogen chloride from chloroethylbenzene, dehydration of phenylethyl alcohols, and decarboxylation of cinnamic acid. Homologues of styrene and substituted styrenes have been made by applying these reactions to analogous compounds. Also its synthesis from acetylene has been attempted.

Styrene occurs ready-formed in coal-tar light-oil fractions and in drip-oil of carburetted water gas. It constitutes a nuisance in motor benzol and in various industrial gases on account of its gum-forming tendencies. Removal of this and other gum-formers would be welcomed by manufacturers of gases and might also serve as a source of synthetic resins.

**Styrene From Chlorinated Hydrocarbons.** At present the most satisfactory process for producing styrene starts with ethylbenzene,<sup>230</sup> a hydrocarbon which is conveniently made by passing ethyl chloride into benzene in the presence of aluminum chloride or from ethylene<sup>231</sup> and benzene. Ethylbenzene when chlorinated below 30°C. gives a mixture of  $\alpha$ - and  $\beta$ -chloroethylbenzene. Passage of the chlorinated hydrocarbon, without separation through a nichrome tube heated to 675-700°C. results in splitting out of hydrogen chloride to yield styrene.<sup>232</sup> Instead of utilizing thermal decomposition, chloroethylbenzene may be treated with pyridine at 100-230°C.,<sup>233</sup> with pyridine or dibenzylamine hydrochlorides or with a cyclic tertiary amine.<sup>234</sup>

Smith<sup>235</sup> concentrated the chloroethylbenzene before treatment with pyridine by distilling off the unchanged ethyl benzene through a column. In this way a more

highly concentrated styrene solution was obtained. Dorrough<sup>231</sup> formed the quaternary salt of pyridine and chloroethylbenzene and heated it at 375-400°C. Chloroethylbenzene may also be heated with inorganic catalysts, such as mercury salts or zinc chloride,<sup>237</sup> with strong acids, such as sulphuric or phosphoric,<sup>238</sup> or with weak organic acids.<sup>230</sup> Passage of  $\alpha$ -chloroethylbenzene over active carbon at atmospheric pressure and at 260°C. is another method.<sup>240</sup> Zal'kind, Berkovich and Amusin<sup>241</sup> chlorinated ethyl benzene at 70°C. in the presence of phosphorus pentachloride as a catalyst. This yielded styrene on boiling with quinoline, or by hydrolysis with dilute soda solution, followed by dehydration with dilute acid potassium sulphate solution. Bromoethylbenzene gives styrene by heating under ordinary pressure.<sup>242</sup>

Analogues of styrene may be obtained by heating the corresponding chloroethylbenzene derivatives with nitrogen-bases or their salts,<sup>243</sup> or with weak, difficultly volatile acids, such as boric, chloroacetic or palmitic.<sup>244</sup>

Deluchat<sup>245</sup> used quinoline for elimination of hydrogen bromide from *o*- or *m*-dibromodiethylbenzene to obtain *o*- and *m*-divinylbenzene.<sup>246</sup> *p*-Divinylbenzene may be prepared by a similar reaction.<sup>247</sup> A good yield of styrene is obtained by brominating ethylbenzene to styryl dibromide and treating the latter with magnesium.<sup>248</sup>

1,1-Dichloroethylbenzene, formed by the action of phosphorus pentachloride on acetophenone, breaks down on boiling in petroleum ether to give  $\alpha$ -chlorostyrene, a compound which resinifies easily.<sup>249</sup>

**Styrene from Hydrocarbons.** When ethylbenzene is passed through an iron tube heated at approximately 650°C., styrene is formed by elimination of hydrogen. The efficiency of the process may run as high as 32 per cent. Cracking of the various homologues of benzene such as xylene, yields styrene to the extent of about 6 per cent.<sup>250</sup> 1,3,5-Dimethylethylbenzene decomposes into 3,5-dimethylstyrene, whereas methylethylbenzene gives methylstyrene.<sup>251</sup> Berthelot<sup>252</sup> passed a mixture of ethylene and benzene through a red-hot tube and isolated styrene from the products of pyrolysis.

Instead of splitting off hydrogen, some hydrocarbons yield styrene by the elimination of methane or other hydrocarbon of low molecular weight. Cymene is said to give well over 50 per cent of *p*-methylstyrene.<sup>253</sup>

Styrene is formed in the vapor-phase cracking of petroleum and at least some natural gases.<sup>254</sup> When petroleum is passed through a reaction tube with a stream of carbon dioxide or other inert gas at a temperature of 650°C., about 6 per cent of styrene is obtained.<sup>255</sup> One way of isolating styrene from the crude distillate, or from any other mixture, is to heat the solution for about 16 hours at 200°C. Polystyrene is formed and is recovered by steam distillation. It can be reconverted to styrene by heating at 350-500°C.<sup>256</sup> Styrene may be separated from a mixture with ethylbenzene by cooling the solution to a low temperature and filtering off the crystallized material.<sup>257</sup>

Vapor-phase cracking of aromatic hydrocarbons in the presence of dehydrogenation catalysts is a more efficient method. A mixture of ethylbenzene and steam may be led at 650°C. over silica gel, active carbon, or lime and magnesium oxide.<sup>258</sup> Styrene or vinyl naphthalene is produced when the vapor of ethylbenzene or ethyl naphthalene is passed at reduced pressure over cerium, copper, iron or zinc oxides heated at about 700°C.<sup>259</sup> The procedure can be improved by preliminary heating of the catalysts in nitrogen, hydrogen or steam.<sup>260</sup> Tungsten, molybdenum or uranium oxides act as promoters for other catalysts or they may be used alone. Various homologues of styrene are obtained when diethylbenzene, ethylbiphenyl, isopropylbenzene, ethyltoluene or the product of the reaction between propylene and benzene are decomposed.<sup>261</sup>

A mixture of benzene and ethylbenzene may be heated in the presence of hydrogen-acceptors, such as sulphur or a mixture of sulphur and ethylene dichloride, which favor dehydrogenation by combining with the hydrogen as fast as it is formed.<sup>262</sup> Ethylbenzene was also passed through a chromel tube at 675-725°C. in the presence of sulphur-free halogens or organic halides, such as ethylene chloride and carbon tetrachloride, to obtain styrene with a concentration of about 40 per cent.<sup>263</sup>

**Styrene by Dehydration of Alcohols.** Distillation of  $\beta$ -phenylethyl alcohol over anhydrous potassium hydroxide yields styrene almost quantitatively.<sup>264</sup> In like manner, distillation of p-diethylolbenzene gives p-divinylbenzene,<sup>265</sup> and  $\alpha$ -ethylolnaphthalene produces  $\alpha$ -vinyl naphthalene.<sup>266</sup> Dehydration with potassium

<sup>266</sup> I. Palfrey, S. Sabatay and D. Sontag, *Compt. rend.*, 1932, 194, 2065; *Chem. Abs.*, 1932, 26, 4325. According to D. Sontag (*Compt. rend.*, 1933, 197, 1130; *Chem. Abs.*, 1934, 28, 2349), distillation of  $\beta$ -ethylolnaphthalene leaves a resinous residue as a result of partial dehydration to  $\beta$ -vinyl naphthalene and polymerization of the latter. The  $\alpha$ -vinyl naphthalene form (D. Sontag, *Ang. chem.*,

hydroxide of a mixture of the o- and p-bromo derivatives of  $\beta$ -phenylethanol, obtained by bromination of the alcohol, gives o- and p-bromostyrene, which polymerize to light-colored resins.<sup>267</sup> Further experiments have shown<sup>268</sup> that the bromostyrene formed in this manner is very stable to heat and shows little tendency to polymerize. Substitution of chlorine for bromine in this treatment results in a chlorostyrene which is also little polymerized by heat. Nuclear substitution of halogens is effected by reacting in the cold in the presence of iron filings or iodine, the nuclear halogen atom not being affected by potassium hydroxide treatment. Formation of the mercaptans from the bromide compounds and subsequent potassium hydroxide treatment yielded styrene in the case of the  $\beta$ -phenylethylbromide, and also a small amount from the  $\alpha$ -isomer, contrary to the results experienced with the  $\alpha$ -alcohol. Von Braun and Neumann<sup>269</sup> obtained a polymer of o-divinylbenzene by treating the quaternary compound of methyl iodide and o-di-( $\beta$ -dimethylaminoethyl)-benzene with alkali. When  $\beta$ -phenylethyl phenylacetate is distilled styrene is formed.<sup>270</sup> Deluchat<sup>271</sup> produced o- and m-divinylbenzene respectively from o-di- $\alpha$ -bromopropylbenzene and m-di- $\alpha$ -bromoethylbenzene.

Distillation of  $\alpha$ -phenylethyl alcohol (phenylmethylcarbinol) over anhydrous potassium hydroxide does not give styrene, but the passage of this alcohol over alumina, thoria or tungsten oxide at 250-400°C. produces that compound in 90 per cent yield.<sup>272</sup> Phenylmethylcarbinol may also be dehydrated by heating it with phosphoric acid or by distilling its benzoic ester.<sup>273</sup>

Smith and Niederl<sup>274</sup> obtained o-vinylphenol by the reaction of phenol and ethylene oxide in the presence of concentrated sulphuric acid. It is assumed that hydroxyethyl phenyl ether is first formed and that this becomes dehydrated and undergoes rearrangement.

Styrene was procured from  $\alpha,\beta$ -dibromodiethyl ether and ethyl ether by means of the Grignard reaction, using magnesium phenyl bromide in ethereal solution. The ingredients were mixed and then refluxed 0.5 hour on the water bath.  $\beta,\beta$ -Ethoxyphenylethyl bromide was produced and converted into styrene by treatment with a zinc-copper couple.<sup>275</sup>

**Styrene by Decarboxylation of Acids.** Bonastre<sup>276</sup> isolated styrene in 1831 by distillation of liquid storax where it occurs in mixture with various cinnamic derivatives. Dragon's blood was also an early source of the compound.<sup>277</sup> When cinnamic acid is heated with barium hydroxide,<sup>278</sup> or when copper cinnamate<sup>279</sup> is heated, styrene is obtained. If cinnamic acid is treated with hydrogen bromide and the resulting bromo-acid boiled with soda solution, styrene is produced almost quantitatively by elimination of hydrogen bromide and carbon dioxide.<sup>280</sup> Careful distillation of cinnamic acid is a convenient method for its preparation.<sup>281</sup>

1934, 1, 359; *Chem. Abs.*, 1934, 28, 4716) is more apt to polymerize than the  $\beta$ -isomer, which is a solid with an intense odor of thymol.

4-Hydroxy-3-methoxycinnamic acid when heated gives an oil (assumed to be 4-hydroxy-3-methoxystyrene) which resinifies easily.<sup>282</sup>

**Styrene from Acetylene.** Acetylene would seem to offer a source of styrene but no satisfactory process has been evolved as yet using this substance. Berthelot<sup>283</sup> found a small quantity of styrene among the pyrolytic products of acetylene. Also the reaction between acetylene and benzene in presence of aluminum chloride has been attempted. Varet and Vienne<sup>284</sup> reported an 80 per cent yield by this reaction but this has never been verified. On the contrary, Cook and Chambers<sup>285</sup> found only traces of styrene, and Böeseken and Adler<sup>286</sup> using a highly reactive preparation of aluminum chloride, obtained a product that was insoluble in all solvents and therefore was not polystyrene. It is known that aluminum chloride is a polymerization catalyst for styrene but the polymer thus formed is soluble. Böeseken and Adler<sup>286</sup> considered their product to be the polymer of a very reactive compound  $C_6H_5$  formed from acetylene and benzene, and called it *polyprotostyrene*. By introducing acetylene into a suspension of aluminum chloride in dry benzene what is described as a cuprene-like substance is obtained, an amorphous mass insoluble in all solvents.<sup>288</sup> Thus, the reaction of acetylene and benzene<sup>289</sup> does not yield styrene.<sup>290</sup> However, 2,4-dihydroxystyrene is the first product formed from acetylene and resorcinol in presence of a mercury catalyst. It forms an insoluble resin on standing.<sup>291</sup>

The Friedel-Crafts reaction of benzene and vinyl chloride yields neither styrene nor polystyrene.<sup>292</sup> Asym-diphenylethane, 9,10-dimethyldihydroanthracene and an anthracene-type resin are formed.

**Miscellaneous Sources of Styrene.**<sup>293</sup> Styrene was early recognized as a constituent of crude xylene.<sup>294</sup> Muller and Langedijk,<sup>295</sup> after prolonged boiling of a specimen of crude xylene, distilled it and obtained a residue of polystyrene equivalent to 17.9 per cent of the mixture. Styrene also occurs in distillates from brown-coal tar.<sup>296</sup>

<sup>289</sup> J. S. Reichert and J. A. Nieuwland (*J.A.C.S.*, 1923, 45, 3090) prepared unsym-diphenylethane by passing acetylene into benzene in the presence of concentrated sulphuric acid and a mercuric salt. Cf. J. A. Reilly and J. A. Nieuwland, *J.A.C.S.*, 1928, 50, 2564.

<sup>290</sup> p-Xylylene dibromide in toluene solution reacts with sodium by the Wurtz reaction to give an insoluble and infusible polymeric hydrocarbon of the same empirical formula,  $(C_8H_8)_n$ , as the product from acetylene and benzene. (See R. A. Jacobson, *J.A.C.S.*, 1932, 54, 1516.) In this case the structure of the polymer is assumed to be a long chain of p-xylylene groups,  $(-CH_2C_6H_4CH_2-)_n$ . Another insoluble polymer of the same empirical formula is noted in the product obtained by treating phenylethyl chloride with aluminum chloride, which may be represented by the formula,  $(-C_6H_4C_2H_4-)_n$ . (See J. v. Braun and H. Deutsch, *Ber.*, 1912, 45, 1268.) The reaction product of benzene and acetylene may be of the same type and consist of chains of the group:  $(-C_6H_4-C_2H_4-)_n$ . These several products differ from polystyrene in having benzene rings as links of the chain molecule.

A considerable amount of styrene is found in carburetted water gas<sup>297</sup> and it is present in the light oil obtained in the manufacture of water gas to the extent of 1.5 to 2 per cent.<sup>298</sup>

In the presence of oxygen in the gas, styrene and similar constituents, such as indene and cyclopentadiene, polymerize to form resins which deposit in gas mains and on the leather diaphragms of gas meters. Such substances are admittedly industrial nuisances and gas manufacturers welcome all efforts to remove these gum-forming materials. It has been estimated that there is a potential supply in the United States of 8,000,000 pounds per year of styrene in the drip-oil of carburetted water gas.<sup>299</sup> Brown<sup>300</sup> suggested its recovery from this source by fractionation of the oil. However, the cost of collection would appear to be prohibitive.

The resinous material formed by polymerization and oxidation of the unsaturated compounds in manufactured gas is called *liquid-phase gum* and occurs mainly in carburetted water gas and mixed gases.<sup>301</sup> Another type known as *vapor-phase gum* results from reaction of gum-forming compounds with oxides of nitrogen.<sup>302</sup> The latter type is formed in the gas phase and is finely dispersed in the gas. It occurs mainly in coal and coke-oven gases.<sup>303</sup> The gum particles are for the most part highly charged and tend to coalesce, finally dropping out of suspension.<sup>304</sup>

The addition of phenols to gases has been suggested as a means of preventing gum deposits in gas mains.<sup>305</sup> Phenols are generally negative oxidation and polymerization catalysts. The removal of oxides of nitrogen also aids in preventing gum formation in gas.<sup>306</sup>

#### POLYMERIZATION OF STYRENE DERIVATIVES

Substitution in the benzene nucleus of styrene gives compounds having the same polymerizing tendency as styrene itself, and it may be even more pronounced. On the other hand, substitution in the ethylene side chain greatly lessens this tendency, depending somewhat upon the kind of group that is introduced. Resin-forming ability should be judged not only by the ease in which polymers form but also by the size of the molecules thus produced. In cases where molecular weight data are lacking, the physical properties of the polymer indicate the degree of polymerization. High polymers are tough; low polymers are brittle. Also soluble polymers of high molecular weight are precipitated from their solutions, when a non-solvent is added, in the form of soft flocks or fibers. Compounds of low molecular weight come down as finely crystalline or amorphous powders.

The effect of a methyl group may be illustrated by comparing styrene compounds containing this group in the ring and in the side chain. o-Methylstyrene polymerizes more readily than the unsubstituted compound, and p-methylstyrene rapidly forms a tough, elastic, resinous material when heated.<sup>307</sup> Also m-methyl-

According to A. Engelhardt and H. Rüping (*Gas- u. Wasserfach*, 1933, 76, 478; *Brit. Chem. Abs. B*, 1933, 611), the active charcoal method of removing benzol from illuminating gas is more efficient than the wash-oil method, and also removes more of the gum-forming constituents from gas. For further information regarding treatment of styrene-containing gases, see W. W. Odell, U. S. P. 1,925,151, Sept. 5, 1933 and 1,926,048, Sept. 12, 1933; *Chem. Abs.*, 1933, 27, 5520, 5944. Also D. styrene solidifies when allowed to stand or when heated.<sup>308</sup> These compounds stand in contrast with  $\alpha$ -methylstyrene (isopropenylbenzene) which does not polymerize at ordinary temperature either on long standing or by the action of light. When stannic chloride is added a violent reaction occurs but the degree of polymerization is not high, a mixture of polymers ranging from the dimer to the octamer being produced.<sup>309</sup> The effect of a methyl group on the  $\beta$ -carbon is noted from the behavior of  $\beta$ -methylstyrene (propenylbenzene), which is converted to a low polymer (apparently the dimer) when boiled with metallic sodium.<sup>310</sup> Indene has a structure which would suggest a  $\beta$ -substituted styrene. However, the ease with which it polymerizes shows that it is more nearly related to *o*-methylstyrene, although it does not form extremely high polymers. (See Chapter 5.)

When heated alone propenylbenzene does not polymerize. Also it does not polymerize when heated with catalysts like stannic chloride. However, in the presence of boron fluoride a clear, brittle resin is formed. *p*-Methoxy- and *p*-ethoxy-propenylbenzene polymerize more easily and mild catalysts are effective. In no case does the reaction go as rapidly as with styrene, nor can eucolloids be obtained. The structure of polypropenylbenzene has been assumed to be:

However, viscosity determinations indicate a chain length 50 per cent greater than is apparent from cryoscopic determination of molecular weight. Therefore, instead of a 1,2 addition as was formerly supposed it is suggested that 1,3 addition occurs:

The mechanism of this reaction involves the wandering of a terminal hydrogen atom in the side chain:

Proof that the polymerization reaction is different than with styrene is indicated by the products obtained by cracking polypropenylbenzene. Besides the monomer, a small amount of 1,4-diphenylbutadiene is present.<sup>310a</sup>

Many styrene derivatives have been studied which contain groups in the benzene nucleus. In most cases polymers of high molecular weight are formed. p-Ethylstyrene<sup>311</sup> when heated to its boiling point changes slowly to a viscous liquid which solidifies on cooling. 2,4-Dimethylstyrene<sup>312</sup> produces a tough, elastic polymer which is insoluble. p-Isopropylstyrene polymerizes more easily than styrene itself.<sup>313</sup> 2,4,5-Trimethylstyrene shows considerable thickening when heated at its boiling point,<sup>314</sup> but sym-trimethylstyrene polymerizes more slowly, although it forms a resin when treated with concentrated sulphuric acid.<sup>315</sup> p-Chlorostyrene<sup>316</sup> and o-bromoethylstyrene<sup>317</sup> change readily to solid forms on standing. p-Nitrostyrene when heated gives a polymer which is insoluble in all solvents.<sup>318</sup>  $\beta$ -Nitrostyrene forms an amorphous solid when treated with alkaline materials such as sodium malonic ester<sup>319</sup> or ammonia, hydrazine and sodium methylate.<sup>320</sup>

Phenyl groups on the side chain greatly limit the size of the polymer. In the absence of oxygen, asym-diphenylethylene forms no polymer higher than the dimer.<sup>321</sup> However, there are two possible dimers, one unsaturated and the other saturated. The first is 1,1,3,3-tetraphenyl-1-butene and the second is 1,1,3-triphenyl-3-methylhydriene.<sup>322</sup> Oxidation of asym-diphenylethylene leads to an insoluble polymeric product.<sup>323</sup> Diphenylene-ethylene is rapidly converted by heat or light

to an amorphous powder, possibly tribiphenylene-cyclohexane.<sup>324</sup> Acenaphthylene yields polyacenaphthylene,  $(C_{12}H_8)_{22}$ , on being heated above its melting point.<sup>325</sup> This is soluble in benzene and is precipitated as a colorless, amorphous powder when alcohol is added. In a benzene solution stilbene forms a dimer under the influence of light.<sup>326</sup> On exposure to light and air, resinous products are obtained besides benzoic acid.<sup>327</sup> In the presence of maleic anhydride, stilbene yields a heteropolymer<sup>328</sup> of a high molecular weight, but by itself it has rather mild polymerizing tendencies. These phenylated derivatives,<sup>329</sup> which form relatively low polymers, may be contrasted with the analogous  $\alpha$ -naphthylethylene ( $\alpha$ -vinyl-naphthalene)<sup>330</sup> which forms well-defined resins.

#### PHENOLIC STYRENES

o-Hydroxystyrene<sup>331</sup> on standing resinifies to a glass-like mass, insoluble in alkalis. When treated with concentrated sulphuric acid a dark red resin is formed. It is doubtful whether the degree of polymerization in this resin is very high since the phenolic group would be expected to act as a negative catalyst. o-Hydroxystyrene may be compared with cumarone which resinifies easily. (See Chapter 5.)

When o-methoxystyrene is heated at 150°C. it polymerizes and, when cold, is a transparent mass.<sup>332</sup> p-Methoxystyrene forms highly polymerized resins. When the reaction occurs at low temperatures the resin molecule may contain as high as a thousand monomeric groups.<sup>333</sup> Of the three methoxystyrenes, the meta- compound polymerizes most readily, then the ortho-, and finally the para-compound.<sup>334</sup> Vinyl derivatives of phenols or cresols are made by reacting vinyl halides with the aromatic compounds in the presence of aluminum chloride or other metallic halides. These may then be polymerized by heat or ultraviolet light.<sup>335</sup>

Eugenol, safrole and methylchavicol undergo very little polymerization. However, when heated with alcoholic potash their allyl groups are rearranged to propenyl groups, giving the so-called iso-compounds,<sup>336</sup> isoeugenol, isosafrole and anethole, respectively. These are methyl-substituted styrenes and as such they show mild polymerizing tendencies, at least much greater than the parent substances. Grognot<sup>337</sup> resinified eugenol in oil of cloves by treatment with phosphorus pentoxide. A brittle product resembling colophony resulted, with indications that some oxidation had occurred.

Polyanethole can be prepared from anethole in various ways. It occurs only in a hemicolloidal form. Treatment of anethole with stannic chloride yields the polymer as a white amorphous powder containing about 30 monomeric groups per molecule.<sup>338</sup> This is in contrast with p-methoxystyrene, noted above, whose molecule lacks substitution on the  $\beta$ -carbon of styrene and which therefore can yield eucoloidal forms. A colorless resin has been obtained as a residue in distilling p-propenylphenol.<sup>339</sup>

Ciamician and Silber<sup>340</sup> compared the action of safrole and isosafrole when exposed to sunlight. To both, traces of iodine were added and after protracted exposure the safrole was found to distil almost completely with steam, leaving only a trace of resinous material, while isosafrole was converted into a brittle brown resin. From 38 g. of isosafrole, 34 g. of resin were obtained. Methyleugenol similarly treated was unchanged but isomethyleugenol yielded a yellowish-brown, almost solid mass. Thirty-five g. of the iso-compound produced about 33 g. of resin, which dissolved completely in ether and made a sort of varnish. Whitby and Katz<sup>341</sup> used stannic chloride as a polymerization catalyst for isosafrole and isoeugenol. They found the molecular weights of the polymers prepared at ordinary temperatures to be about 2000. Prepared at about 200°C., the polymers showed half this molecular weight. The polymers are unsaturated. Eugenol and safrole give the same type of resins as the iso-compounds but the reaction goes much more slowly. Kronstein<sup>342</sup> heated safrole, eugenol, isosafrole and isoeugenol,

vinyl-3,4-pyrocatechol methylene ether

in the absence of oxygen, to temperatures below their decomposition points. He obtained polymerized substances, soluble in alcohol and ether, resembling natural soft resins. Heavy camphor oil undergoes a similar change. When safrole is passed at 500°C. over kieselguhr, it yields resinous products.<sup>343</sup>

Vanillin is obtained by hydrolysis of the ozonide of isoeugenol. Manufacturers of synthetic vanillin seek to avoid the formation of resin during the ozonation and hydrolysis of the ozonide. Resin formation is lessened by conducting the ozonolysis at a low temperature.<sup>344</sup> Methylation of the phenolic group is also effective.<sup>345</sup> Treatment of isoeugenol dissolved in toluene results in less resinous material than when the reaction is conducted in aqueous emulsion.<sup>346</sup> Harries<sup>347</sup> was able to limit resinification by treating the ozonide with potassium ferrocyanide in acetic acid solution. The ozonides of safrole and isosafrole decompose spontaneously at ordinary temperatures with formation of resins.<sup>348</sup>

Electrolytic oxidation of isoeugenol and vanillin in a 15 per cent solution of caustic soda yields resinous masses.<sup>349</sup> Resins are also formed by oxidation of isoeugenol in sodium sulphate solution with an anode of lead peroxide, unless the phenol group is protected by methylation.<sup>350</sup>

## Chapter 12

# Miscellaneous Resins From Hydrocarbons and From Phenols. Certain Tars

### HYDROCARBON-ALDEHYDE RESINS

The interaction of aromatic hydrocarbons with aldehydes has been known at least since 1872 when Baeyer<sup>1</sup> condensed benzene and formaldehyde. Similar work was done by others at this time. Substances used included benzene, toluene, mesitylene, diphenyl, naphthalene, formaldehyde, acetaldehyde, methylal, and chloral.<sup>2</sup> The compounds obtained were generally of the diarylmethane type, and little or no account was taken of resin-forming tendencies in these condensations.

Nastyukov<sup>3</sup> condensed formaldehyde and benzene in the presence of sulphuric acid and obtained an insoluble amorphous solid which he found to be very stable to oxidizing agents. Repeating the experiment with naphthalene he decided that this type of condensation product was characteristic of unsaturated cyclic hydrocarbons and the percentage weight isolated was denoted as the "Formolite Number" of an oil so treated.<sup>4</sup> The same method was used by Arnold<sup>5</sup> in his investigation of low-temperature tar oils.

However, it was about 1907 that aromatic hydrocarbons, particularly naphthalene, became prominent as useful starting materials for resin production by virtue of their condensation with formaldehyde. It was reported that the products were soluble in oils, in hydrocarbons, in their chloro derivatives, and in some cases even in drying oils. Bohn<sup>6</sup> devised several procedures for making such resins. The following is an example of one of them:

To a solution of 8 parts of 30 per cent formalin, or its equivalent of methylal, in 115 parts of 97 per cent sulphuric acid is added 10 parts of naphthalene. The reaction is carried out for about 1½ hours at 110°C., in which time the mixture thickens. Treatment of the cooled product with water removes the catalyst and with benzene and alcohol removes any unchanged hydrocarbon. A bright yellowish-brown resin is finally obtained.

Bohn stated that the use of one molecular proportion (or greater) of formaldehyde yielded resins of higher melting point than those obtained with smaller

proportions.<sup>7</sup> It was suggested that the products could be used in making varnishes and sealing wax.<sup>8</sup>

Hydrocarbons were condensed with formaldehyde (40 per cent) in the presence of concentrated sulphuric acid (sp. gr. 1.84) in a process employed by Bayer & Co.<sup>9</sup> The acid formed less than 60 per cent of the mixture. At 110-115°C. naphthalene yielded a white resin, soluble in acetone, benzene, solvent naphtha, carbon tetrachloride and carbon disulphide. Phenanthrene gave a brownish-yellow, brittle resin, soluble in benzene and xylene; and anthracene, a yellow resin soluble in benzene. Under pressure at 118-125°C., benzene formed a soft brown resinous mass soluble in benzene; toluene, a clear liquid, soluble in ether, acetone, benzene, and carbon tetrachloride; and xylene, a brown resin soluble in acetone, benzene, carbon tetrachloride and solvent naphtha. These products, especially those melting below 100°C., were thought to be of value in varnish making.

Condensation products of naphthalene with formaldehyde, intended for use in the lacquer or varnish industry, were prepared by Folchi<sup>10</sup> as follows:

One hundred grams of naphthalene are added to 80 cc. of 30 per cent formaldehyde, 100 cc. of sulphuric acid (sp. gr. 1.84) gradually added, and the mixture heated under reflux on a water bath at 80°C. for 1½ hours with agitation. The contents of the flask are poured into water at 80-90°C. and the melted condensation product is washed with water, dilute alkali, and with water again. The mass is then dried at 80°C. for 4 to 5 hours. For use as lacquer the material is melted with a small quantity of turpentine and mixed with refined tar. By strict attention to the above reaction conditions a weight yield of 100-110 per cent of the naphthalene used may be obtained. The hardness of the product varies with the temperature of formation. An alternative method is to use 100 grams of naphthalene, 80 grams of 40 per cent formaldehyde, and 120 grams of sulphuric acid, heating for 3 hours at 90-95°C. In this case the yield is 80-90 per cent. Folchi stated that the action of formaldehyde on unsaturated aliphatic hydrocarbons gave rubbery masses and the action on aromatic hydrocarbons gave materials similar to phenol-aldehyde resins.

La Vingtrie<sup>11</sup> mixed a naphthalene-formaldehyde resin with rubber, and by vulcanizing with sulphur obtained an ebonite. The resin was prepared as follows: 1 part of naphthalene is dissolved in 2 parts of concentrated sulphuric acid and heated with 3 parts of 13 per cent formalin at 140°C. in an autoclave. The product is purified by washing with water and caustic soda solution. Depending on conditions, the resin may have a melting point of 100°C. and be soluble in such solvents as carbon tetrachloride, or it may be an insoluble powder. A similar reaction was carried out by Aimond.<sup>12</sup> Naphthalene was converted into its sulphonic acid, using concentrated sulphuric acid, and then condensed with formaldehyde at 140°C. to yield a resin (Naphthoform A) which was infusible and insoluble. When introduced into ebonite it speeded the vulcanization. It was discovered that if the naphthalene was first treated with formaldehyde, and then mixed with sulphuric acid, the resulting resin (Naphthoform B) was fusible, melting at 100-120°C.

The last-noted examples have all used sulphuric acid as catalyst, but other catalysts have been found effective in some cases. For instance, aromatic hydrocarbons, or derivatives, are heated with aldehydes, preferably in a solvent such as acetic acid, with the use of such limited proportions of phosphoric or halogen

<sup>7</sup> R. Bohn, German P. 207,743, 1907, to Badische Anilin- & Soda-Fabrik; *J.S.C.I.*, 1909, 28, 431. British P. 16,245, 1907. French P. 386,664, 1908; *J.S.C.I.*, 1908, 27, 457, 695.

acids that products soluble in linseed oil are obtained.<sup>13</sup> By using as condensing agents organic acids such as formic, oxalic or lactic, and varying the amount of formaldehyde used, the products will range from viscous oils to brittle resins. Other condensing agents include sodium bisulphate, stannous chloride, zinc chloride,<sup>14</sup> calcium chloride and magnesium sulphate.<sup>15</sup> Hydrocarbon derivatives which have been used are phenetole, anisole, diphenyl ether, m-cresol ethyl ether,  $\alpha$ -naphthyl ethyl ether and  $\beta$ -naphthyl ethyl ether.

Experiments performed in the author's laboratory<sup>16</sup> have demonstrated that resinous products are obtained when benzene and formaldehyde are condensed with zinc chloride and hydrogen chloride. Dry hydrogen chloride was passed for 25 minutes at 65°C. through a well-stirred mixture of benzene (200g.), 40 per cent formalin (35g.) and zinc chloride (50g.). The reaction product was subjected to steam-distillation to remove liquid components, leaving as a residue a dark violet, nearly black resin (yield 40%), insoluble in alcohol and acetone.

Benzaldehyde has been used in place of formaldehyde for condensation when the cyclic hydrocarbon contains eight or more carbon atoms.<sup>17</sup> Condensing technical xylene, or solvent naphtha, with benzaldehyde in the presence of concentrated sulphuric acid at less than 20°C. for 24 hours yields an oily product. This oil is steam-distilled to remove unaltered hydrocarbons, and the wax-like still-residue is purified by extraction with benzene. The resulting resin is a viscous mass.

Hydrogenated naphthalenes have also been utilized in condensations with aldehydes, forming products which can be incorporated with linseed oil and turpentine in varnish manufacture.<sup>18</sup> Using phosphorus pentoxide as a catalyst, tetrahydronaphthalene will condense with paraformaldehyde to form a light-colored resin, and a viscous oil, the latter probably ditetrahydronaphthalene.<sup>19</sup> The use of inorganic acids in place of phosphorus pentoxide will produce more resin and less oil.

Morgan and Harrison<sup>20</sup> have made resins by condensing acenaphthene with formaldehyde. In experimental work 26 g. of acenaphthene and 5 g. of paraformaldehyde were dissolved in 450 cc. of glacial acetic acid at 25°C. Into this was stirred a mixture of 4.2 cc. of concentrated sulphuric acid and 9 cc. of glacial acetic acid. The liquid quickly developed a light blue color, and in a few minutes a white solid began to precipitate. After 5 days the solid was washed with water and dried (yield 25 g.). The resin had a melting point of 126-128°C. and was soluble in chloroform, benzene, and carbon tetrachloride, but insoluble in alcohol. It was found that fluorene and indene produced resins when similarly treated. 4-Chloroacenaphthene, when treated with formaldehyde as above, produced a resin, and also when heated with alkali it produced tarry material (m.p. 210-215°). In experiments by Lorrimer,<sup>21</sup> gummy products were obtained when acenaphthene, dissolved in benzene, was treated with a mixture of acetic anhydride and the reaction product of phthalic anhydride and aluminum chloride.

Indene was condensed with formaldehyde by Claasz,<sup>22</sup> as follows: A mixture of 100 parts of indene, 100 parts of formalin (30 per cent), and 5-10 parts of concentrated hydrochloric acid is boiled under reflux for 5 hours, yielding a layer of

thick, clear oil, which becomes viscous when washed and cooled. When exposed to air it acts somewhat like a drying oil.

The condensation of 1-chloronaphthalene with formaldehyde in the presence of acids was found to yield clear elastic resins useful in varnishes and in the preservation of leather.<sup>23</sup> It was also found that chloronaphthalenes will condense with themselves or with aromatic hydrocarbons if aluminum chloride or ferric chloride is used as a catalyst. These resins are soluble in oils but not in alcohol. Beer<sup>24</sup> noted that 1-chloronaphthalene or its methyl homologues, or chlorinated anthracene could be condensed with less than 10 per cent of formaldehyde in sulphuric acid at a temperature below that at which the hydrocarbon is ordinarily sulphonated. The resins were soluble and could be used as wetting, dispersing and emulsifying agents, and as solvents for fats and oils.

Bosshard and Strauss<sup>25</sup> observed that naphthalene will condense when it is heated with dehydrated oxalic acid and aluminum chloride at 100°C. Treatment of the reaction product with hydrochloric acid, and subsequent steam distillation to remove excess naphthalene yielded a brittle, reddish brown resin (m.p. 95°) resembling colophony.<sup>26</sup> The use of ferric chloride instead of aluminum chloride resulted in a blackish brown pulverulent mass (m.p. 180°C.). These resins were used in varnishes and as impregnating agents.

Similarly, a condensation of naphthalene is effected by heating it with glycollic acid and phosphorus pentoxide.<sup>27</sup> The reaction is carried out by heating this mixture under pressure for 15 hours at 130-170°C., allowing carbon dioxide to escape from the apparatus from time to time. Steam distillation of the reaction product removes unchanged naphthalene and leaves behind a yellow resin (m. p. 80-85°C.) resembling shellac. Aromatic hydrocarbons may be converted into resins by first decomposing them with sulphuric acid using phosphorus pentachloride or sulphur dichloride as a catalyst, and then condensing the products directly with polyhydric alcohols, e.g., glycerol.<sup>28</sup>

Anthracene and phenanthrene, in the presence of aluminum chloride in aromatic hydrocarbons (benzene, toluene or m-xylene), undergo autocondensations, and also condensations with the aromatic hydrocarbons.<sup>29</sup> In the autocondensations, very active hydrogen is released which causes the formation of low-melting tarry by-products. However, if dry oxygen is passed through the reaction mixture, the active hydrogen is oxidized, and the resins obtained have higher melting points.

Resins have been formed by condensing benzene, ethylbenzene, isopropylbenzene or butylbenzene with a symmetrical ethylene dihalide using aluminum chloride as catalyst.<sup>30</sup>

In the methylation of xylene to form durene, pentamethylbenzene and hexamethylbenzene, Smith and Dobrovolsky<sup>31</sup> found that the synthesis of hexamethylbenzene was hindered by the formation of dark tars from condensed rings and from the decomposition of hexamethylbenzene. Red, tarry material was obtained<sup>32</sup> in an attempt to convert pentamethylbenzene into hexamethylbenzene and 1,2,3,4-

tetramethylbenzene (prehnite) by the action of sulphuric acid (the Jacobsen reaction).

A resinous hydrocarbon of the formula  $(C_7H_8)_n$  was obtained by Sabatier and Maible<sup>32</sup> by the dehydration of benzyl alcohol with metallic oxides at temperatures of 250-350°C. Analogous to this is the reaction of 1 volume of benzyl alcohol with 2 volumes of sulphuric acid trihydrate to form a mixture of hydrocarbons which on distillation yielded a yellow, fluorescent resin.<sup>34</sup>

#### WATER SOLUBLE PRODUCTS

The replacement of natural products by synthetic resinous substances has affected the leather industry, and tanning operations can be carried out with material obtained from the condensation of formaldehyde with either sulphonated hydrocarbons or sulphonated phenols.<sup>35</sup> These products are also useful as wetting agents.

A tanning agent was made by Schmidt<sup>36</sup> in the following manner: Naphthalene and sulphuric acid are heated together at 140°C. forming  $\beta$ -naphthalene sulphonic acid. After cooling and maintaining the temperature at 60-100°C., formaldehyde is added gradually. Then, as the mass thickens, water is added to facilitate stirring. On cooling, the product solidifies to a resinous, slightly colored, water-soluble mass. The resin can be used directly as a tanning agent, or it can be added to the difficultly soluble tanning extracts such as quebracho, chestnut, or mangrove to increase their solubility and efficiency. Kämpf<sup>37</sup> used the sulphonic acids of aromatic hydrocarbons or their condensation products with aldehydes and ketones in the preparation of spinning-baths for viscose solutions. Egner<sup>38</sup> mixed formaldehyde-naphthalene sulphonic acid condensations with dried products from the nitric acid oxidation of peat or lignite. This material tanned leather to a light color.

A water-soluble condensation product useful as a tanning agent was made by Jaeger.<sup>39</sup> Sulphonated hydrocarbons were condensed with carbohydrates and then further condensed with formaldehyde, and the product converted into the sodium salt. Hydrocarbons used in this process were crude anthracene and naphthalene, and the carbohydrates included cellulose from old sulphite paper, cotton rags or wood pulp, or soluble sugars or starches. When crude hydrocarbons are used the products are sometimes highly colored, this being an objectionable feature in some cases. The color can be removed by oxidizing the material with hypochlorites, chlorine, chromic acid or potassium permanganate.<sup>40</sup> Sulphonated hydrocarbon mixtures produced by treating crude naphthalene, or anthracene oil, are condensed with formaldehyde in a process by Moeller<sup>41</sup> to produce tanning agents. In place of sulphonated hydrocarbons a crude acid resin can be used, provided sufficient naphthalene or anthracene is added to it to use up the excess sulphuric acid in the resin.

A type of wetting or dispersing agent has been obtained by condensing

$\beta$ -naphthalene sulphonic acid with benzoic acid and an alcohol using sulphuric acid as a condensing agent.<sup>42</sup> The product, after washing with water, neutralizing with caustic soda and precipitating with sodium chloride, is a grayish-white powder, soluble in water. Similarly, the sulphonated products of mineral oil fractions when condensed with alcohols have yielded wetting-out agents or emulsifiers.<sup>43</sup>

#### RESINS FROM REDUCTION AND OXIDATION OF AROMATIC HYDROCARBONS

**Reduction.** Although experiments under this heading would hardly be expected to lead to any resinous products, the explanation of such resin formation may be that the partially hydrogenated intermediate compounds polymerize more rapidly than they absorb hydrogen.

Naphthalene and anthracene, when hydrogenated under 190-250 atmospheres pressure at 350-490°C., yielded tetrahydro derivatives, liquids resembling benzene and high-boiling, pitchy decomposition products.<sup>44</sup> Aluminum chloride as a catalyst increased the yield of liquid, but not of pitchy products. Schroeter, Müller and Huang<sup>45</sup> found that although pure phenanthrene hydrogenates smoothly to di-, tetra- and octahydro derivatives, technical phenanthrene is converted by sodium and amyl alcohol into di- and tetrahydro compounds and a considerable portion of resinous material. Maible<sup>46</sup> observed that during the reduction of benzene and its methyl homologues to methane at 270-280°C. in the presence of nickel, a resin soluble in acetone was deposited on the catalyst. Ipatiev, Orlov and Dolgov<sup>47</sup> have done considerable work on the hydrogenation and dissociation of aromatic hydrocarbons under pressure, and have obtained, in many cases, resinous substances as by-products.

**Oxidation.** In experiments by Ono,<sup>48</sup> naphthalene was oxidized electrolytically to  $\alpha$ -naphthaquinone with the formation of small quantities of phthalic acid and some dark-brown resinous matter. The electrolysis was carried out in acid solution using lead peroxide and platinum as the positive pole. The resinous matter contained phenolic hydroxyl groups.

Fichter and Herszbein<sup>49</sup> found that electrolytic oxidation of  $\alpha$ -methylnaphthalene in sulphuric acid solution produced a resin (yield 37%). In corresponding experiments Fichter and Meyer<sup>50</sup> obtained resinous material by the electrochemical oxidation of m-xylene emulsified with sulphuric acid, and of cymene in sulphuric acid-acetone solution.

Austin and Black observed that the Tesla discharge converted benzene vapor into biphenyl, and toluene into bibenzyl.<sup>51</sup> In addition, in each case resinous products similar to shellac were formed. The resin had a deep reddish brown color and was apparently formed by condensed molecules of a phenolic type, the necessary oxygen having been derived from water molecules, since the hydrocarbons were not absolutely dry. This work was a continuation of earlier work by Aus-

tin<sup>52</sup> and by Harkins and Gans<sup>53</sup> on the behavior of hydrocarbon vapors in the electrodeless discharge. In these experiments resinous deposits were formed but they contained no oxygen. [Formula (CH)<sub>n</sub>.] Similarly, benzene in the brush discharge yielded a resinous product (C<sub>6</sub>H<sub>4</sub>)<sub>n</sub>, in experiments by Davis.<sup>54</sup>

Fowler and Mardles<sup>55</sup> found that an electric spark passing between carbon electrodes below the surface of liquid benzene decomposed the latter with the formation of a thick yellow liquid.

The action of canal rays on hydrocarbon vapors was studied by Kohlschütter and Frumkin.<sup>56</sup> With a cathode fall of 200-400 volts, all the hydrocarbons used (benzene, naphthalene, anthracene, biphenyl, phenanthrene) formed a deposit of decomposition products on the cathode. Subsequent heating of this deposit *in vacuo* at 500°C. caused the formation of a sublimate of tar. Becker<sup>57</sup> found that decalin (C<sub>10</sub>H<sub>18</sub>) and tetralin (C<sub>10</sub>H<sub>12</sub>) both yielded drying resins when subjected to an electrical discharge in a Siemens ozone tube.

Studying the stability of hydrocarbons in an acetic acid solution of hydrogen peroxide, Charrier and Moggi<sup>58</sup> noted that benzene reacted slowly, though prolonged action under reflux yielded carbon dioxide and a yellow resin. Naphthalene reacted much more quickly, producing phthalic acid and a resin. Phenanthrene gave the quinone and then diphenic acid and a resinous material. Gelissen and Hermans<sup>59</sup> in their studies of the action of dibenzoyl peroxide on benzene and toluene obtained considerable resinous material. The resin from benzene contained carbon (80%), hydrogen (6%) and oxygen (14%). In the case of toluene the addition of aluminum chloride or ferric chloride to the reaction mixture increased the speed of the reaction and decreased the yield of resinous matter. These workers disagreed with the explanations made by Lippmann<sup>60</sup> who performed some of the primary work on this reaction. Berthelot<sup>61</sup> found that the oxidizing action of sunlight was sufficient to convert benzene into a resinous product.

In attempts to oxidize crude anthracene to anthraquinone it was discovered that phenanthrene, dissolved in nitrobenzene, yielded resinous products when oxidized with oxides of nitrogen.<sup>62</sup> Melamid<sup>63</sup> noted that the oxidation of anthracene oil (b.p. 300-350°C.) when effected with a mixture of sulphuric acid and potassium bichromate or permanganate at -20 to -15°C. using a solvent such as benzene gave a resin, and an oil which could be used in electric transformers. Rubrene (C<sub>42</sub>H<sub>38</sub>), when treated with chromic oxide oxidized to a resin, in experiments performed by Dufrasse and Enderlin.<sup>64</sup>

Experiments on the oxidation of methylbenzenes such as toluene, m-xylene, mesitylene, durene and cymene were carried out by Stephens<sup>65</sup> by bubbling dry oxygen through the dry, purified hydrocarbons in dim, diffused light at about 100°C. In every case an aldehyde and the corresponding acid were formed, and in addition a considerable quantity of a reddish brown resin.

Vollman<sup>66</sup> observed that tetrahydronaphthalene on exposure to the air becomes yellow and to a certain degree resinifies like turpentine. Wittig and Leo<sup>67</sup> in studies on hexasubstituted ethanes noted that *p,p'*-bis(diphenylmethyl)diphenylmethane and the corresponding substituted ethane both formed resins when oxidized by contact with the air. The fulvene of  $\beta$ -ionone is a viscous, orange-colored hydrocarbon of the formula  $C_{18}H_{24}$ . On exposure to the air the compound absorbs oxygen and forms a resinous mass.<sup>68</sup>

#### RESINS FROM REDUCTION AND OXIDATION OF PHENOLS

**Reduction.** In experiments on the pyrogenous dissociation of aromatic compounds under pressure of hydrogen and in presence of catalysts Ipatiev and Orlov<sup>69</sup> observed that after four hours heating at 500-550°C. under 60 atmospheres of hydrogen, diphenyl ether yielded a little benzene, 3 per cent phenol, and about 30 per cent of a non-volatile, viscous, black resin, the remainder being unchanged material. In the presence of alumina at 480°C., the reaction yielded 15 per cent benzene, 9 per cent phenol, but no resin. When heated under the same conditions but with a mixture of aluminum and cupric oxides, neither phenol nor *o*-cresol gave any resin. Some 20 per cent of the phenol employed was reduced to benzene. Catechol, however, yielded 75 per cent phenol, 10 per cent benzene and 15 per cent of a brittle brown resin. Working with Dolgov, Ipatiev<sup>70</sup> isolated several crystalline compounds and a considerable amount of resin from the reduction of  $\beta$ ,  $\beta$ -dihydroxydinaphthylmethane under 100 atmospheres of hydrogen in the presence of nickel at 250°C.

**Oxidation.** The rapid discoloration by air of alkaline solutions of phenols is a commonplace observation, and the well-known estimation of oxygen in gas analysis is based on the extreme rapidity with which pyrogallol absorbs oxygen under such conditions. Photograph development is based on a similar property of hydroquinone. Fischer<sup>71</sup> and co-workers, in particular, have made a study of these reactions and found that the products formed could be readily obtained as resins useful for a variety of purposes, such as ingredients in paint and varnish preparations. For instance, dissolving phenol in concentrated aqueous ammonia solution and treating with air, using copper as a catalyst, a black solution was obtained which dried to a viscous syrup and finally to a varnish-like product.

Pummerer<sup>72</sup> oxidized phenol or its homologues in alkaline solution with potassium ferricyanide, or in acetic acid solution with lead dioxide, or with ferric chloride. The brown, resinous products so obtained were further polymerized by treatment with alkalis, acids, or heat. Reduction or acylation of these products improved their color and rendered them insoluble in alkali.

By bubbling moist air through cresols or xlenols for about 10 hours at 150-170°C. in the presence of traces of manganese dioxide or ferric chloride, resinous substances have been obtained.<sup>73</sup> Unchanged material is removed by steam distillation. Both the duration of the heating and the reaction temperature affect the quality of the resulting products, which are usually dark brown to black masses, ranging in consistency from soft to hard brittle resins. The softer products are converted into highly lustrous, hard and brittle resins on further heating. The resins are soluble in dilute caustic soda solution but are not soluble in sodium carbonate. They are soluble in some organic solvents, e.g., ether, alcohol, acetone

and benzene but are insoluble in cold turpentine. The softer resins are readily soluble in fatty oils but the hard resins go into solution very slowly. The resinification is thought to be brought about by oxidation of the alkyl groups of the phenols and subsequent polymerization of the resulting intermediate reaction products, this second reaction occurring either among the intermediate products themselves or with unchanged phenols.

Bunge<sup>74</sup> prepared resins by oxidizing phenols in primary monohydric alcohols using as catalysts palladium, platinum or the salts of vanadium. As an example, phenol in methyl alcohol is heated under 20 atmospheres of oxygen in an autoclave using an alkaline solution of a vanadium salt as catalyst.

Magidson and fellow-workers<sup>75</sup> obtained resinous material when oxidizing phenol with sodium peroxide in sulphuric acid solution in an attempt to produce pyrocatechol and hydroquinone. The use of hydrogen peroxide to oxidize anisole to guaiacol caused the formation of much resinous material, formed apparently from the condensation of the guaiacol under the influence of the oxidizing agent.

Voss<sup>76</sup> found that certain oily condensation products could be converted into resins by oxidation. Passing air or oxygen at temperatures of 160-190°C. into the condensation products of phenol and benzyl chloride, naphthalene and benzene chloride, and tricresol and xylyl chloride, he obtained brown resins, suggested for lakes, insulators and varnishes.

Cresol is used as an absorption liquid for solvent recovery in the Brégeat system.<sup>77</sup> Its prolonged use however results in the contamination of the cresol with considerable amounts of resin, thereby lowering the efficiency of the cresol.<sup>78</sup> It was found that this resinification was caused by the presence of volatile acids, industrial dust and various peroxides. It was observed by Triebs<sup>79</sup> that the resinification of phenols by air-oxidation is catalyzed by the presence of iron, lead, bismuth, cobalt, nickel, copper or aluminum. He also noted that cresol resin so obtained contains less oxygen than the original cresol, because of the formation of water in the oxidation.

Goldschmidt, Schulz and Bernard<sup>80</sup> obtained a brown resin (30% yield) by oxidizing o-cresol with lead dioxide in a mixture of moist ether and acetic acid at -10°C. Analysis and molecular weight determinations indicated the formula  $C_{11}H_{10}O_2(OH)$ . The presence of the hydroxyl group was shown by the solubility of the resin in caustic soda and by methylation with dimethylsulphate. In an attempt to synthesize a perhydrobenzophenanthrene, Schrauth and Görig<sup>81</sup> obtained a resin as the result of oxidizing with phosphorus pentoxide a mixture of phenol and o-cyclohexyl-cyclohexanol. The resin was dark brown in color and solidified to a glassy, transparent mass. When applied to wood, it formed a lac-like coating.

#### ELECTROLYTIC OXIDATION

Bartoli and Papasogli<sup>82</sup> on electrolyzing solutions of phenol in potassium and sodium hydroxides with coke, graphite and platinum electrodes, obtained an acid

having the composition  $C_7H_6O_4$  (m.p.  $93^\circ\text{C}$ ). With retort coke as the positive electrode an extensive decomposition of phenol occurred and a resin was formed. Electrolysis of an emulsion of symmetrical-m-xylol in 2*N*-sulphuric acid, and also in acetone yielded m-xyloquinone and a resin. The latter was obtained in larger yield when an o-xylene solution of the xylol was treated similarly.<sup>83</sup> In a high vacuum this resin yielded a fraction corresponding in composition to a dixylenol ( $C_{12}H_{10}O_2$ ). Electrochemical oxidation of thymol also yielded some resin.<sup>84</sup>

#### OXIDATION UNDER PRESSURE

A more extensive investigation of oxidation of phenols to resins was made by Fischer and Schrader,<sup>85</sup> by using air under 45 atmospheres pressure. They were seeking to obtain substances similar to phenol-aldehyde resins from the phenols of low temperature tar without the addition of formaldehyde. The bodies obtained consisted partly of insoluble condensation material and partly of degradation product. Under some conditions fairly clear resinous substances were obtained, the color being dependent on the temperature and concentration of the mixture. Phenol at  $100^\circ\text{C}$ . in a 2.5*N*-caustic soda solution yielded a considerable quantity of brown resinous material, though less at  $150$ – $200^\circ\text{C}$ . The three isomeric cresols, oxidized in caustic soda solution, yielded coloring matters and degradation products but little resinous matter. The former were apparently fuchsine derivatives resulting from the condensation of cresol with aldehydes. In *N*-sulphuric acid above  $150^\circ\text{C}$ . cresol was extensively oxidized, yielding solid substances. At  $150^\circ\text{C}$ . the products were a hard lustrous orange-colored resin, soluble in benzene and alcohol, a brown substance insoluble in benzene, and small quantities of coloring matter.

Fischer<sup>86</sup> obtained yellow resinous material or asphalt-like substances by heating one molecular proportion of a phenol dissolved in an excess of 2.5*N*-caustic soda solution at about  $200^\circ\text{C}$ . and under 40 atmospheres pressure of either oxygen or air. Dilute sulphuric acid may be used instead of the alkali.

#### PRESSURE TREATMENT OF COAL-TAR PHENOLS

Fischer, Gluud and Breuer<sup>87</sup> heated low-temperature tar, its fractions boiling below and above  $300^\circ\text{C}$ ., and the phenols and neutral oils of these fractions separately under pressure in contact with steel wool in an autoclave at  $320^\circ\text{C}$ . for two successive periods of three days each. After this treatment, the tar itself and the hydrocarbons had a higher viscosity and density and a higher setting point than before. The phenols thickened more rapidly and to a greater extent than the hydrocarbons, giving pitch or asphalt-like products.<sup>88</sup>

Low-temperature tar and also the fraction distilling below  $270^\circ\text{C}$ . were subjected by Fischer and Ehrhardt<sup>89</sup> to pressure oxidation in a continuous stream of air at  $150^\circ\text{C}$ . and 40 atmospheres pressures. The product was a black, lustrous, pitchy substance partly soluble in benzene. To determine whether the hydrocarbons, as well as the phenols, were oxidized, the hydrocarbons were treated

<sup>83</sup> F. Fichter and M. Rinderspracher, *Helv. Chim. Acta*, 1927, 10, 102; *Brit. Chem. Abs. A*, 1927, 353.

<sup>84</sup> F. Fichter and A. Christen (*Helv. Chim. Acta*, 1925, 8, 322; *J.C.S.*, 1925, 128 (1), 813) obtained resinous substances in the electrolytic oxidation of 4-hydroxy-3-methoxypropenol.

<sup>85</sup> F. Fischer and H. Schrader, *Ges. Abhandl. Kennt. Kohle*, 1910, 4, 293; *J.S.C.I.*, 1921, 40, 340A.

<sup>86</sup> F. Fischer, *British P.* 149,979, 1920; *J.S.C.I.*, 1922, 41, 22A. *German P.* 347,521, 1922.

<sup>87</sup> F. Fischer, W. Gluud, and P. K. Breuer, *Ges. Abhandl. Kennt. Kohle*, 1917, 2, 222; *Chem. Abs.*, 1920, 14, 2071.

<sup>88</sup> A. Hageman and M. Neuhaus (*Braunkohle*, 1931, 30, 949; *Chem. Abs.*, 1933, 27, 2017) have stated that the tendency of tar phenols to condense under pressure increases with molecular weight.

<sup>89</sup> F. Fischer and U. Ehrhardt, *Ges. Abhandl. Kennt. Kohle*, 1919, 4, 280; *Chem. Abs.*, 1921, 15, 2713.

separately. This treatment produced a clear, limpid oil and also a reddish yellow oil which deposited solids when cooled, and when exposed to the air, dried like varnish. Thus it was indicated that the hydrocarbons were attacked but to a lesser extent than the phenols. In an oxidation carried out at 100°C. the hydrocarbons of a 270°C. fraction were scarcely attacked, whereas the phenols were extensively changed to resins and acids. It was suggested that the oxidation products of low-temperature tar can be used in paints and varnishes.

In these experiments lead oxide was found to have no catalytic effect on the oxidation, though some light was shed on the behavior of lead phenolate paints. In other studies on lead phenolates, Fischer and Ehrhardt found that crude tar oils could be oxidized with lead oxide. The oxidation products, when distilled with potassium permanganate or nitric acid, gave varnish-like materials.<sup>90</sup>

Resinous black printing colors were obtained when tar oils or tars were oxidized with oxygen under pressure using catalysts such as aluminum, iron, vanadium oxide, ferric chloride or sulphur chloride.<sup>91</sup> Kárpáti<sup>92</sup> obtained solid condensation products possessing good electric insulating properties when he oxidized under pressure tar distillates (boiling up to 230°C.) containing a high proportion of creosote.

#### BASIC LEAD PHENOLATES

A curious type of resin obtained by the action of litharge on phenols has been extensively investigated by Fischer and Ehrhardt.<sup>93</sup> Lead oxide dissolves readily in phenol with a strong evolution of heat, and, on cooling a gelatinous mass results. In water a basic lead phenolate separates, which when heated above 100°C. is transformed into a viscous product that may be drawn into threads and on cooling yields a glassy mass. These investigators attempted to utilize the product for varnishes and paints. Its films are brittle, and on protracted exposure show indications of formation of lead oxide at the surface. The resin prepared from phenol itself when applied as a coating to a surface will crystallize in the course of a few days and become worthless. Lead oxide likewise combines with cresol, parahydroxybiphenyl and the naphthols. The higher the molecular weight the less is the tendency to crystallize, and quite durable coatings were obtained from lead oxide and  $\alpha$ -naphthol. Phenols from the crude phenol-rich fraction (middle oil) of low temperature tar or coke oven tar yield products which have been found useful for protecting ironwork from rusting.

In preparing this lead compound, lead oxide is added to the phenol at about 120°C., in quantity only sufficient to give the basic compound, and the additions are made in small portions with stirring, since the resinous compound is decomposed by overheating. The product may then be thinned with benzene or solvent naphtha, or the diluent (of sufficiently high boiling point) may be present during the reaction.

Ordinary phenol (4.7 parts) and lead oxide (10.8 parts) in benzene (20 parts) yielded a solution which gave a glassy coating on drying, but in two days was cloudy, becoming crystalline and powdering readily. A cresol mixture known as liquid carbolic acid (5 parts) with lead oxide (10.8 parts) in benzene (20 parts) yielded a coating which became crystalline in the course of a few days. *p*-Hydroxybiphenyl (8.5 parts) and lead oxide (10.8 parts) gave a good coating which was unchanged for months.  $\alpha$ -Naphthol (7.2 parts) and lead oxide (10.8 parts) yielded a varnish which was slightly greenish in color after drying. The coating showed no tendency to crystallize and appeared quite resistant to weathering influences.  $\beta$ -Naphthol gave a softer product but did not darken. Phenolphthalein was unaffected by lead oxide.

Phenols from low temperature tar (b.p. 200-270°C., 200 cc.) mixed with lead oxide, (125 grams) and heated to 120°C., reacted violently causing the temperature

<sup>90</sup> F. Fischer and U. Ehrhardt, *Ges. Abhandl. Kennt. Kohle*, 1919, 4, 264; *Chem. Abs.*, 1921, 15, 3559.

<sup>91</sup> German P. 364,830, 1920, and its addition 367,495, 1920, to Rütgerswerke A.-G.; *J.S.C.I.*, 1923, 42, 614A, 731A.

to rise to 140°C. The mixture was finally heated to 155°C. and subsequently thinned with 150 cc. of benzene. A rather durable varnish was obtained. Phenols boiling between 200-250°C. similarly treated with lead oxide gave a dull varnish which did not crystallize.

#### TREATMENT OF CERTAIN TARS

By extracting Russian peat with a benzene-alcohol mixture, up to 24 per cent of bitumen can be obtained.<sup>94</sup> This bitumen when treated with solvents is divided into two fractions, yellow or brown crystalline waxes soluble in light petroleum and black resins soluble in benzene. Polymerization of the resins takes place when the bitumen is heated to 180°C., yielding substances insoluble in organic solvents.

To improve the quality of tars by making them more plastic and increasing the speed of drying, the tars are treated with aldehydes and oxidizing gases using ammonia as catalyst. A similar result is obtained by incorporating with the tars a synthetic resin having an aldehydic base.<sup>95</sup>

When an intermediate distillate from gilsonite is purified with sulphuric acid and then sulphonated with fuming sulphuric acid a semi-drying viscous oil is obtained, after washing out excess acid. Mixing the oily product with linseed oil causes it to dry homogeneously rather than with the formation of a surface film.<sup>96</sup>

By treating coal-tar pitch (1000 parts) preferably containing montan wax (2 parts) with steam and hydrogen under 3-8 atmospheres pressure in presence of ferric oxide (8 parts) and chloride (5 parts), Rahmann<sup>97</sup> secured a heavy anthracene oil (80 parts) at 240-300°C., and both a yellowish wax and a reddish resin (together 370 parts) at 300-360°C. The resin and wax may be used as obtained, or may be mixed with 3 to 20 per cent of montan wax, paraffin or ceresin, and used in the manufacture of dyes, varnishes and impregnating materials.

By allowing petroleum asphalt to interact in an inert solvent with sulphuric acid or aluminum chloride, Lechler<sup>98</sup> obtained a product with greater stability and higher softening point than the original asphalt. This material was suggested for the manufacture of paints or emulsions. Tar oils, tars and pitches containing crude phenols, were used by d'Antal<sup>99</sup> to form resins by mixing them with vegetable oils or bituminous substances and heating with sulphuric acid. The resinous masses obtained in this way when mixed with fillers are said to be useful for molding articles or for structural material.

Fischer, Horn, and Küster have used lignite directly for moldings by mixing with phenols.<sup>100</sup> Lignite or lignitic brown coal, pulverized and vacuum dried, is kneaded at 80°C. with 12 per cent of its weight of cresol in a volatile solvent. Swelling occurs and when this has ceased the solvent is removed by vacuum distillation. The resulting material when pressed at about 150°C., under 4000 lbs. per square inch is named "Kohmit." It is stated to be a better electrical insulator than ordinary phenol-aldehyde resin and only slightly inferior to it in mechanical strength, and the cost of raw materials is about 10 per cent of the cost for phenol-aldehyde resin. In place of phenols the substitution of organic bases (e.g., aniline, pyridine,

quinoline) gave favorable results. The plasticity and strength of the material was found to be improved by the addition of small amounts of rubber. The plastic is stable, odorless, and non-melting; it is readily machined and can be used for making buttons and plates.

The neutral oils of low-temperature lignite tar, extracted with methyl alcohol, and treated with mercuric acetate at 100°C., yielded mercurous acetate, mercury and resins in experiments performed by Benthin and Ruhemann.<sup>101</sup>

Stuer and Grob<sup>102</sup> have studied the results of passing mixtures of acetylene with various gases such as ammonia, hydrogen sulphide and steam over catalysts. They found that at 350°C. steam and acetylene when passed over bog iron ore yielded a mixture of aldehydes, ketones, alcohols, phenols, and tar and resinous materials. From this mixture a good resin solvent could be obtained by fractional distillation.

By heating tar oil hydrocarbons (b.p. above 140°C.) containing 0.5 to 10 per cent of aluminum chloride with acetylene gas, Lihlenfeld<sup>103</sup> obtained viscous oils which when purified by vacuum distillation were reported to be suitable for lubrication or therapeutic purposes. By incorporating them with cellulose ethers and modifying the products by the addition of camphor, cellulose esters, oils or fillers, he obtained substances available for the manufacture of films, filaments, varnishes, insulators, adhesives, and artificial leather.

Jena<sup>104</sup> extracted a varnish resin from bituminous coal by using as solvents either methyl or ethyl alcohol or acetone. A fraction (b.p. 180-230°C.) of low-temperature bituminous coal-tar has been suggested by Ehrmann<sup>105</sup> as a source of raw material for resin and lacquer manufacture.

By extracting lignite with acetone, or other ketones, containing hydrochloric acid, staining solutions for wood are obtained. If cellulose acetate is added the solutions are said to be useful for paints or lacquers.<sup>106</sup>

An acid resin from coal-tar was used by Schuchardt<sup>107</sup> as a binder in briquettes. Liquid components were first removed from the resin by squeezing it between hot rollers and the resin was then mixed with coal dust and tar residues. Another briquette binder is made by benzene extraction of the residues from the pressure hydrogenation of coal.<sup>108</sup>

Sperr<sup>109</sup> has converted coal-tar pitch (m.p. 40°C. or over) into a paint by melting it and mixing it with solvent naphtha at 100-200°C. so that a colloidal solution is formed. The paint is said to be useful for coating iron and steel to prevent corrosion. In studies on tar acids in coal tars, Cheng and Morgan<sup>110</sup> found that the resins present in these tar acids could be extracted by treatment with caustic soda and subsequent precipitation with benzene.

Four types of resins have been isolated from the tars of wood, peat, lignite and bituminous coal:—neutral resinenes, basic resinamines, phenolic resinols and resinic acids.<sup>111</sup>

The resinenes are presumably amorphous mixtures of hydrocarbons. On oxidation with permanganate the resinenes yielded various benzenecarboxylic acids,

e.g., mellitic,  $C_6(COOH)_6$ , mellophanic 1,2,3,5- $C_6H_2(COOH)_4$ , and phthalic acid. The resinamines are amorphous solids insoluble in ether but soluble in alcohol and in dilute mineral acids. They consist of various nitrogen-containing substances. The resinols are amorphous solids of a phenolic nature (m.p. 100-160°C.) amounting to about 3 per cent of the weight of the original tar. The resinoic acids are of a stronger acid nature than the resinols and are soluble in aqueous sodium bicarbonate. In general the resins of low-temperature coal-tar are pale yellow to brown amorphous powders. They are of high molecular weight and are soluble in many organic solvents. Evaporation of such solutions leaves the resins behind as hard, transparent films. The resins furnish wood stains of even tone without raising the grain of the wood.<sup>112</sup>

Morgan<sup>113</sup> and others recovered resins from low temperature coal-tar by first extracting the tar with a solvent such as ether or benzene and then precipitating the resin with petroleum ether or by evaporation of the solvent. These resins were used in lacquers and molded articles.

<sup>112</sup> Considerable resinous material has been found in low-temperature tar from Utah coal. See R. L. Brown and B. F. Branting, *Ind. Eng. Chem.*, 1928, 20, 392. R. L. Brown and R. N. Pollock, *ibid.*, 1929, 21, 234.

# Chapter 13

## Phenol-Aldehyde Resins

### I. Historical

Condensation of phenols with aldehydes yields a large number of products of various properties. Some are crystalline, others are amorphous or resinous. This discussion concerns the resinous bodies only and includes a historical sketch of some of the early investigations of these resins, and of the development work which resulted in making phenol-aldehyde resinous products commercially successful.

**Salicylic Acid.** An insoluble resinous body was obtained by Gerhardt<sup>1</sup> as early as 1853 by dehydrating sodium salicylate with phosphorus oxychloride. The course of the reaction is indicated as follows:

Gerhardt observed that the resin was affected by aqueous caustic potash. Schroder, Prinzhorn and Kraut,<sup>2</sup> in 1869, found that the dehydration of sodium salicylate with phosphorus oxychloride produced a resin which was insoluble in water, alcohol and ether and which when treated with caustic potash could be hydrolyzed to yield salicylic acid.<sup>3</sup> Velden<sup>4</sup> showed that salicylic acid in the presence of sodium amalgam and acid forms hydroxybenzyl alcohol by reduction and then by dehydration becomes a saliretin body. Baekeland<sup>5</sup> also has shown that resinification of this character occurs when salicylic acid is reduced at the cathode by electrolysis.

By condensing salicylic acid with gallic acid Doebner<sup>6</sup> obtained a white amorphous powder which was recommended as an antiseptic. An antiseptic which readily gives off formaldehyde and ammonia was also produced by Speyer<sup>7</sup> from naphthol or polyphenols like resorcinol or pyrogallol and an excess of ammonia and of formaldehyde. This gave an insoluble powder.

**Baeyer's Work.** Any discussion of the resinous condensation products of aldehydes and phenols, lacking reference to the work of Baeyer in 1872 would be incomplete. At this early date Baeyer<sup>8</sup> announced that the reaction between phenols and aldehydes is a general one. He noticed that oil of bitter almonds (benzaldehyde) united with pyrogallallic acid on heating in a manner resembling that of phthalic acid. A colorless resinous substance associated with a red oxidation product was obtained. The colorless resin was formed immediately in the cold when pyrogallallic acid in hydrochloric acid was mixed and well agitated with oil of bitter almonds and hydrochloric acid. Resorcinol and oil of bitter al-

<sup>3</sup> An octa- or nona-salicylosalicylic acid may be formed. The probable linking of the chain is according to the formula  $\text{HO}-\text{C}_6\text{H}_4\text{COO}-(\text{C}_6\text{H}_4\text{COO})-\text{C}_6\text{H}_4\text{COOH}$ . See F. Beilstein and F. Soelheim, *Ann.*, 1861, 117, 87. Also L. V. Redman, A. J. Weith and F. P. Brock, *Ind. Eng. Chem.*, 1914, 6, 3. E. Drabble and M. Nierenstein, *Biochem. J.*, 1907, 2, 96. *Chem. Abs.*, 1907, 1, 1146, noted similarities between resin-like constituents of cork, and salicylic acid condensation products.

monds react in like manner when concentrated sulphuric acid is added gradually to a mixture of them. Thickening occurs and after purification a red resin is obtained. The resin dissolves in concentrated sulphuric acid, forming a water-soluble substance.

When acetaldehyde was added to a mixture of concentrated sulphuric acid and phenol, Baeyer found the mixture to thicken and on the addition of water to yield a white sticky substance. This was soluble in caustic potash affording a violet-colored solution. Aldehyde-ammonia dissolved in hydrochloric acid and mixed with pyrogallol acid in concentrated hydrochloric acid yielded a soft white precipitate, easily soluble in hot water. By heating the aldehyde with pyrogallol and hydrochloric acids a red substance was obtained. Chloral acted similarly to acetaldehyde.

Michael and Comey<sup>9</sup> found that equal parts of acetaldehyde and resorcinol dissolved in 3 parts of alcohol and slightly acidified with hydrochloric acid solidified on heating at 100°C. to a gelatinous mass, insoluble in the usual solvents.

**Benzaldehyde and Phenols.** The reaction between benzaldehyde and phenols was studied by Michael<sup>10</sup> and found to result in various resinous bodies. Phenol and benzaldehyde in alcoholic solution, in the presence of a trace of hydrochloric acid, did not react in the cold but on heating for several hours yielded a resin. Orcinol, resorcinol and pyrogallol react with benzaldehyde in the cold in the presence of hydrochloric acid with the evolution of heat. Salicylaldehyde also reacts with phenol. Resorcinol and benzaldehyde heated in a closed tube to 200°C. form a resin, but heating in open vessels does not bring about a reaction. In the presence of acids, the union takes place far more rapidly. A trace of hydrochloric acid causes the formation of a white amorphous compound. Water may replace alcohol as a diluent. On heating to boiling the aldehyde gradually unites with the resorcinol and is completely converted into a resin. To obtain the resin in pure form, Michael treated a solution of equal parts aldehyde and resorcinol in 3 parts of alcohol with a minute amount of hydrochloric acid, and, after the reaction was complete, allowed the solution to cool and filtered it from crystalline material. The filtrate was poured into water and a white resinous mass precipitated which was extracted several times with a large quantity of cold water, redissolved in a small amount of alcohol and reprecipitated by pouring into water.

All attempts to obtain this body in a crystalline form were without success. The white material remained unchanged in contact with the air when it contained considerable water, but it darkened when the water was removed. Before drying at 100°C. the resin is insoluble in boiling water but melts under it to a reddish mass. It is very soluble in alcohol, benzene, ether and glacial acetic acid. On exposure to the air it gradually takes up oxygen and is converted into a dark brown substance, decomposition taking place very rapidly when the resin is heated. The resin dissolves readily in alkalies and the solutions become discolored quickly on exposure to air. The dried resin is also soluble in alkalies. It melts with complete decomposition at a high temperature, somewhat above 300°C. Michael prepared an acetyl derivative of the resin, a white amorphous substance somewhat less soluble in alcohol and benzene than the parent resin. The acetyl compound was insoluble in alkalies in the cold. Michael found the crystalline material formed in alcoholic solution during the preparation of the resin to be the result of the action of hydrochloric acid on the resin. The activity of acids as catalysts varies with their strength, hydrochloric and sulphuric acid being most active. Phosphoric acid is somewhat less vigorous and organic acids, such as

<sup>9</sup> A. Michael and A. M. Comey, *Am. Chem. J.*, 1883-1884, 5, 349.

<sup>10</sup> A. Michael, *Am. Chem. J.*, 1883-1884, 5, 338.

acetic, formic, lactic and oxalic acids, are much less active. Alkalies also were found to have a catalytic effect; caustic soda, caustic potash and potassium carbonate yielded resins of a similar character. In preparing the resins the solution should be kept as much as possible from the air when employing alkaline catalysts, as oxidation accompanied by darkening takes place.

Trzeinski<sup>11</sup> treated 3 parts by weight of  $\beta$ -naphthol and 1.5 parts of benzaldehyde in 1.5 parts of alcohol with 1 part of concentrated sulphuric acid and obtained a crystalline body, but the same procedure applied to  $\alpha$ -naphthol yielded only resinous products.

**Formaldehyde and Phenols.** Baeyer<sup>12</sup> found that methylene acetate reacted with phenol in the presence of concentrated hydrochloric acid to form a colorless resin. Ter Meer<sup>13</sup> used methylal with certain phenols and likewise obtained condensation products of resinous character which were not further investigated. However by 1890 formaldehyde was a commercial preparation and at the instigation of Emil Fisher investigations were carried out by Kleeberg<sup>14</sup> on its condensation products with phenols. Kleeberg found that formaldehyde reacts energetically with phenol, resorcinol and pyrogallol in the presence of concentrated hydrochloric acid to yield products which are insoluble in alkalies and are so difficult to purify that their composition could not be determined. With gallic acid a compound of a more definite character was produced, an acid  $C_{16}H_{12}O_{10}$ , apparently being the result of a union of two molecules each of gallic acid and formaldehyde with the elimination of water:

Kleeberg's experiments with gallic acid consisted in treating a hot aqueous solution of 20 g. of the acid with 40 cc. of commercial formaldehyde solution, concentrated hydrochloric acid being added until the solution became turbid. On cooling a small amount of a brown resin and a larger quantity of a colorless amorphous substance separated, which was particularly investigated by Kleeberg. It was found to be very difficultly soluble in all common solvents but easily soluble in fixed alkalies and aqueous ammonia. The condensation product proved to be an acid which when purified was amorphous and colorless. On strong heating it carbonized without melting.

Kleeberg mixed 10 g. of phenol with 20 cc. of a 40 per cent aqueous formaldehyde solution and added concentrated hydrochloric acid with cooling. Reaction took place with the evolution of considerable heat and a rose-red viscous mass formed which solidified on cooling. The pulverized product was extracted by boiling with water and alkalies until the color had disappeared completely. The purified product was practically insoluble in all of the common solvents and in caustic alkali solutions. On heating, it carbonized without melting. Analysis of various preparations made according to the foregoing gave no concordant results and Kleeberg concluded that the substance was a mixture of complex condensation products possessing no phenol group. It is evident that here in Kleeberg's grasp was the principle of our present-day resinoids (see Chapters 1 and 14).

Hosaeus<sup>15</sup> referred to unpublished investigations carried out by Tollens, who heated dilute formaldehyde solutions with phenol, resorcinol, pyrogallol and phloroglucinol with the addition of sulphuric or hydrochloric acid. In all cases resinous products separated which were either difficultly soluble or insoluble in all common

<sup>11</sup> W. Trzeinski, *Ber.*, 1884, 17, 499; note also *Ber.*, 1883, 16, 2335.

<sup>12</sup> A. Baeyer, *Ber.*, 1872, 5, 1094.

<sup>13</sup> E. ter Meer, *Ber.*, 1874, 7, 1700.

<sup>15</sup> H. Hosaeus, *Ber.*, 1892, 25, 3212.

solvents. Hosaeus himself treated  $\beta$ -naphthol with formaldehyde solution in the presence of acetic acid and obtained a crystalline product. Abel<sup>18</sup> investigated the reaction between formaldehyde and the naphthols and in general obtained crystalline substances. Menthol also yielded a crystalline body. Guaiacol when treated with formaldehyde and excess of guaiacol eliminated yielded a brittle yellowish mass soluble in alkalis.

Litterscheid and Thimme<sup>17</sup> treated phenol and resorcinol with monochlorodimethyl ether,  $\text{CH}_3\text{—O—CH}_2\text{Cl}$ , and obtained insoluble bodies which they described as having the appearance of porcelain and which they compared with the products obtained by Baeyer<sup>19</sup> from phenol, a formaldehyde derivative and hydrochloric acid.

Breslau and Pictet<sup>20</sup> condensed phenol and aqueous formaldehyde in the presence of concentrated sulphuric acid, subsequently neutralizing, distilling and extracting the product with ether. The purified material (b.p. 197–200°C.) was thought by them to be methylene glycol methyl phenyl ether since the same compound was obtained by condensing potassium phenate and monochloro-dimethyl ether.

**Acids of Guaiac Resin.** An interesting research was carried out by Doebner<sup>20</sup> on the synthesis of the acids of guaiac resin (guaiacum). The three acids

found in this resin contain the radical  $\text{CH}_3\text{CH}=\text{C}\begin{array}{l} \text{CH}_3 \\ \text{OCH}_3 \end{array}$  present in tiglic aldehyde and also the guaiacol radical  $\text{—C}_6\text{H}_3\begin{array}{l} \text{OH} \end{array}$  The three acids of the

natural resin appeared to differ essentially with respect to the number of hydroxyl groups present.

Doebner mixed 5 parts of tiglic aldehyde with 9 parts each of guaiacol and cresol diluted with 20 parts of glacial acetic acid, added 2 parts of concentrated hydrochloric acid and heated the mixture for 20 minutes on a water bath. The mixture was poured into about 250 parts of strong hydrochloric acid and heated for 15 minutes longer, then poured into cold water. A brown resin separated which was purified by distillation with steam. This removed the excess of guaiacol and cresol. The resin was further purified by dissolving it in dilute caustic soda and precipitating with dilute acid. It was found to be soluble in alcohol. The purified resin was of a yellowish-brown color apparently an isomer of guaiac resin. Its constitution is represented by the following formula:

By condensing tiglic aldehyde with guaiacol and pyrogallol dimethyl ether, a somewhat similar resin was obtained. Tiglic aldehyde and dimethylpyrogallol yield a resin of the composition represented by the formula  $\text{C}_{27}\text{H}_{20}\text{O}_6$ . Doebner

therefore drew the conclusion that the natural guaiac resin is a condensation product of phenols with aldehydes.

**Phenol Alcohol or Saligenin.** (Ortho-Hydroxybenzyl alcohol.) As the phenol alcohol, saligenin, plays an important role in the formation of the resinous condensation products of phenol and formaldehyde a discussion of the chemistry of this compound finds appropriate place here. Saligenin represents the simplest condensation product of phenol and formaldehyde.<sup>21</sup> Being a crystalline substance it has been prepared in a pure state. Its melting point is 82°C. Manasse in making it used as condensing agents various inorganic basic substances, namely caustic soda and caustic potash, potassium and sodium carbonate, quicklime, zinc and lead oxides, also zinc dust, sodium acetate and potassium cyanide. Lederer<sup>22</sup> used milk of lime or baryta water.

The phenol alcohol is conveniently made by dissolving phenol in somewhat more than an equivalent amount of dilute caustic soda solution. An equivalent amount of formaldehyde (40 per cent aqueous solution) is added and the mixture is allowed to stand until the odor of formaldehyde has disappeared. Then the solution is neutralized with acetic acid and extracted with ether to remove the phenol alcohols and the uncombined phenol. The latter may be removed by distillation with steam. Both the o- and p-hydroxybenzyl alcohols form. Manasse<sup>23</sup> suggested that these alcohols may be formed in one of two ways: the formaldehyde in alkaline solution may act as methylene glycol, CH<sub>2</sub>(OH)<sub>2</sub>, according to the following reaction:

or, a simple aldol transformation may take place through formation of the alcohol group by the transfer of one hydrogen atom of the phenol.

The separation of the two hydroxybenzyl alcohols was carried out by Manasse as follows: the ether extract of the crude product is dried by sodium carbonate and the solution evaporated to dryness. A yellowish oil is obtained which crystallizes after standing for a few days. The crystalline mass is treated with benzene at 50°C., which extracts o-hydroxybenzyl alcohol. From this solution the alcohol can be readily crystallized. Auwers and Daেকে<sup>24</sup> observed that p-hydroxybenzyl alcohol which has not been well purified may become resinous on standing.

Similar hydroxy alcohols are formed from certain other phenols: thymol, for example, giving a crystalline product which on being warmed in the presence of mineral acids resinifies. By treating the alcohol with concentrated sulphuric acid and diluting with water a resin is precipitated.

**Saliretin.** Piria prepared this resin by the action of dilute acids on saligenin.<sup>25</sup> Saliretin may be prepared by warming 1 part of the glucoside, salicin C<sub>6</sub>H<sub>11</sub>O<sub>6</sub>—O—C<sub>6</sub>H<sub>4</sub>—CH<sub>2</sub>OH, with 10 parts of hydrochloric acid (sp.gr. 1.25) to 80°C., precipitating with water, dissolving the precipitate in moderately dilute alcohol and

precipitating the solute with brine.<sup>26</sup> Saliretin is a yellowish powder soluble in alcohol and alkalis. Moitessier<sup>27</sup> pointed out that saligenin on losing 1 molecule of water by dehydration passes over into a saliretin resin. The saliretin obtained from saligenin by Gerhardt<sup>28</sup> with sulphuric acid corresponds to the formula,  $C_{24}H_{20}O_8$ ; that is, it may be looked upon as derived from 4 molecules of saligenin by the loss of 3 molecules of water. By heating saligenin with acetic anhydride or with ethyl iodide Beilstein and Seelheim<sup>29</sup> obtained a saliretin of the composition,  $C_{20}H_{16}O_8$ , the result of withdrawal of 7 molecules of water from 8 molecules of saligenin.

Baekeland<sup>30</sup> noted that saligenin or hydroxybenzyl alcohol is very easily dehydrated and that the removal of water brings about the formation of a resinous substance. The dehydration can occur by the mere application of heat and is much hastened by strong acids and certain other chemical agents. Hence to prepare hydroxybenzyl alcohol successfully low temperatures and general careful treatment are essential. The hydroxybenzyl alcohol produced in alkaline solution by the method of Manasse is best isolated by exact neutralization with weak acids and extraction with solvents which separate it from uncombined phenol. Unless such precautions are observed the reaction may get beyond control and resinous bodies may be produced in large proportion. This is especially true when strong acids are used as condensing agents but even under such conditions Baekeland<sup>31</sup> was able to establish the presence of noticeable quantities of hydroxybenzyl alcohol.

The direct homologue of saliretin, which is methyl saliretin or homosaliretin, has properties similar to saliretin, melts at 200-205°C. and is less soluble.<sup>32</sup>

Auwers and Daecke<sup>33</sup> prepared an acetyl compound of dibromo-p-hydroxybenzyl alcohol (m.p., 112-113°C.). When this product was treated with a small amount of caustic alkali and the solution acidified a reddish-brown amorphous substance, melting at 240-250°C. with decomposition, was obtained. This substance was found to be insoluble in all common organic solvents. It formed more readily the more concentrated the solution and the longer the period of action of the alkali. A concentrated alkaline solution of the acetate in the course of a few minutes changed into a violet jelly which consisted entirely of the substance of high melting point.

The substance saliretone  $C_{14}H_{12}O_8$  is obtained by heating equal parts by weight of saligenin and glycerol for 8 hours in a sealed tube on a water bath. The contents of the tube are diluted with water and the precipitated resin is boiled with water. Evidently the reaction progresses largely to a resinous body because the yield of saliretone is given as 2½ per cent on the basis of the saligenin used.<sup>34</sup> Its melting point is 121.5°C. When saliretone is heated above 140°C., or even boiled with water for a long time, a resin is formed which has the empirical formula  $C_8H_6O$  (saliretin?), and is soluble in ether and alkalis.

**Saliretazine.** In 1894 Paal and Senninger<sup>35</sup> carried out some observations on the action of ammonia on saligenin (o-hydroxybenzyl alcohol) which are of especial interest in view of the subsequent development of commercial synthetic resins from phenol and formaldehyde. When saligenin is heated to 180-200°C. with ammonia, a basic condensation product is obtained in the form of a yellow amorphous body which is notably insoluble in acids, alkalis and various organic solvents. An

analysis indicated the formula  $C_{35}H_{35}O_5N$ . The formation of this substance from saligenin and ammonia may be represented by the following equation:

Paal and Senninger tried many solvents on this resin, including ether, alcohols, chloroform, acetone, glacial acetic acid, benzene, phenol and aniline, without finding any indication of its solubility. The substance was infusible and decomposed on heating above  $300^\circ\text{C}$ . This insoluble and infusible amorphous body is of interest in view of its bearing on Bakelite and similar infusible resinoid substances.

**Acetaldehyde and Phenol.** In the course of some experiments on the production of acetals Claus and Trainer<sup>36</sup> observed the action of acetaldehyde on phenol in the presence of hydrochloric acid gas. Because of the violence of the reaction, the following procedure was adopted:

One equivalent of acetaldehyde and 2 equivalents of phenol were dissolved in ether and cooled while hydrochloric acid gas was passed through the solution. Under these circumstances the reaction progressed quietly and after evaporating the ether and water produced by the reaction a reddish, soft, resinous mass remained. Removal of the uncombined phenol by treatment with steam yielded a hard, brittle resin. This product was insoluble in water, benzene and petroleum ether but dissolved easily in alcohol, ether, chloroform, acetone and glacial acetic acid. It was also soluble in a mixture of equal parts of benzene and ether. Efforts were made by Claus and Trainer to crystallize the resin from some of these solvents but no crystalline body could be obtained. The resin dissolved easily in aqueous caustic alkali solutions and on acidification this solution yielded a white or rose-colored precipitate which retained inorganic salts very tenaciously. The precipitated resin could not be obtained free from ash without tedious extraction with hot water or solution in ether. This resinous material began to soften at about  $100^\circ\text{C}$ , and at  $125^\circ$  was viscous. Even at higher temperatures it did not become freely fluid.

An analysis indicated that 1 molecule of the aldehyde had united with 2 molecules of phenol with the elimination of 1 molecule of water. However, instead of forming an acetal, the aldehyde had evidently joined the benzene nucleus through two hydrogen atoms to yield a compound which Claus and Trainer named ethyldenediphenol<sup>37</sup> having the formula:

Claus and Trainer also determined the action of acetaldehyde and hydrochloric acid on the naphthols.  $\alpha$ -Naphthol behaved like phenol in forming ethyldenedi- $\alpha$ -naphthol but  $\beta$ -naphthol apparently formed an acetal. This difference in behavior recalls the work of Beckmann and Dehn on furfural resins (see Chapter 24), where a very great difference was noted in the character of the reaction between furfural and  $\alpha$ - or  $\beta$ -naphthol.

**Molded Insulation by Smith's Process.** It is of interest to note that as early as 1900 phenol-aldehyde resins were proposed for making electrical insulation. Smith<sup>38</sup> made an ebonite substitute as follows:

Two volumes of paraldehyde were diluted with 1 volume of methylated spirit, 3 volumes of carboic acid (liquefied by 5 per cent of water) added and then gradually into this mixture in a closed container 3-6 volumes of fusel oil or methylated spirit saturated with hydrochloric acid were introduced. The mixture was cooled

<sup>36</sup> A. Claus and E. Trainer, *Ber.*, 1888, 19, 3004.

<sup>37</sup> See also R. Fabinyi, *Ber.*, 1878, 11, 283.

<sup>38</sup> A. Smith, U. S. P. 643,012, Feb. 6, 1900; British P. 16,247, 1899; German P. 112,685, 1899; *J.S.C.I.*, 1899, 18, 1029.

to prevent the temperature rising above 80°F. (26.7°C.). The product was poured into greased molds and allowed to set. The shaped articles were removed from the molds and dried or baked at 212°F. (100°C.). When fusel oil was employed as the vehicle for adding hydrochloric acid the product was black. It was found to be resistant to most chemical reagents. Molded articles also were treated, either before or after drying, by gradually heating in molten paraffin wax or ozokerite to 100°C. The temperature of baking reached a maximum during a period of 12-30 hours according to the thickness of the article, and was then slowly reduced. This procedure is somewhat similar to certain methods subsequently employed in cold molding. Twice the quantity of pure acetaldehyde could be used to replace paraldehyde; that is 4 volumes of acetaldehyde to 3 volumes of liquified phenol.

Polymerized formaldehyde dissolved in fusel oil which had been previously saturated with hydrochloric acid or sulphur dioxide was also recommended by Smith. The polymerized formaldehyde, 1 part, was mixed with about 5 parts of acidified fusel oil. Phenol crystals were introduced in an amount sufficient to add 50 per cent to the volume of the mixture. The composition set rapidly and could be shaped or fashioned in a manner similar to that employed with the paraldehyde composition. To any of these compositions 5-10 per cent of natural resins could be added by dissolving them in the gas-saturated fusel oil or methylated spirit before mixing. By slightly reducing the proportion of the gas-saturated alcohol the composition was obtained in a plastic condition capable of being pressed into various forms. Asbestos was used as a filler.

**Shellac Substitutes.** By 1900 a number of investigators were studying the products obtained from the reaction of phenol and formaldehyde. These previously despised resinous products were now examined with a view to seeing what could be done with them. Formerly, when it was established that reaction products could not be crystallized and possessed no definite melting point, they were discarded. Now they were studied to see what new properties they might possess. From a commercial standpoint, a shellac substitute was very attractive at this time and Blumer,<sup>30</sup> seeking such a resin, considered an hydroxy acid to be efficient as a condensing agent. He employed tartaric acid.

The following procedure was recommended: 135 parts by weight of tartaric acid are mixed with 150 parts of a 40 per cent solution of formaldehyde in a spacious jacketed vessel lined with lead. The acid is completely dissolved by heating gently and then 195 parts of commercially pure carbolic acid are introduced. Gentle heat is applied until reaction begins and from then on the heat of the reaction serves to keep the contents of the vessel in ebullition for a period of about 10 minutes. The crude resin is found floating on the surface as an oily material. This is placed in hot water and boiled after adding some ammonia. The treatment serves to eliminate the small quantity of phenol and formaldehyde present. When poured into cold water the resin at once solidifies to a white mass. Two different samples of this phenol resin gave closely agreeing results when subjected to elementary analysis, which agreed with the empirical formula,  $C_{21}H_{20}O_4$ .

Blumer carried out the condensation of  $\alpha$ -naphthol by mixing 155 parts by weight of tartaric acid with 150 parts of aqueous formaldehyde, adding 290 parts of  $\alpha$ -naphthol and permitting combination to take place. The reaction progresses violently and the product is a red resin which sets very quickly to a hard mass. As the resin does not melt in hot water it cannot be purified as phenol resin can, hence Blumer recommended that the resin be pulverized for purification purposes. The resins obtained by Blumer are stated to be suitable for the manufacture of varnishes or polishes because they are readily soluble in various solvents such as alcohol, ether and oil of turpentine. Coatings obtained with these solutions are highly resistant and possess a good luster.

<sup>30</sup> L. Blumer, German P. 172,877, 1902; British P. 12,880, 1902; British P. 6,523, 1903; *J.S.C.I.*, 1903, 22, 705; 1904, 23, 448.

**Luft's Process.** Another worker in this field in the early part of 1900 was Luft.<sup>40</sup> He also used an acid catalyst or condensing agent, recommending sulphuric, hydrochloric or oxalic acids.

For example, he suggested mixing equal parts of phenol and a 40 per cent formaldehyde solution with 0.4-0.8 part of sulphuric acid of 16-17°Bé. The mixture is heated in a vessel equipped with a reflux condenser. Violent reaction takes place yielding a white viscous mass which settles. This is collected, washed and dried. In the fresh condition the resin is plastic but when dried it ultimately becomes brittle. The resin is non-inflammable and is attacked by neither hot concentrated mineral acids nor alkalis. This property, Luft noted, would make it suitable for preparing containers for acids, alkalis and other chemicals were it not for its brittleness. Luft suggested the addition of other substances, such as camphor, rubber, glycerol or even alcohol, all of which, he stated, prevent hardening of the mass. He also remarked that mechanical operations are not without influence on the properties of the resin. A harder and very elastic mass is obtained if the resinous material is pressed in slightly warmed molds.

To render the resin transparent, Luft boiled it (after previous washing with water) while in a viscous condition with a neutralizing agent such as alkaline carbonate. The resin is then washed and dissolved in a mixture of formaldehyde and glycerol. The solution is thickened by boiling, poured into molds and dried at a temperature of about 50°C. Acetone or alcohol may also be used as a solvent. Such solutions, with the addition of coloring agents if desired, give waterproof coatings on fabrics or leather. Luft suggested drawing out the material into threads and carbonizing them for incandescent-lamp filaments.

As the resin is a non-conductor of electricity, Luft proposed its use for insulating purposes. It may also be used, he stated, as a substitute for celluloid and in the manufacture of molded articles, such as billiard balls, buttons and handles, and as an imitation amber, tortoise shell, meerschaum, vulcanite or coral and in making a kind of linoleum.

Baekeland<sup>41</sup> prepared Luft's product and found it relatively brittle and very much less tough and flexible than celluloid. It does not melt if heated, although it softens considerably. Acetone swells it and appropriate solvents extract free camphor and glycerol if these are present. In a controversy with Baekeland, Redman<sup>42</sup> discussed the Luft process, stating that the two steps which resulted in the production of Bakelite consisted in adding the basic condensing agent in certain proportions at the beginning of the reaction instead of after the reaction had proceeded for a short time in an acid solution in accordance with the Luft process, and in the use of increased heat and counter-pressure where necessary to prevent the escape of gases. Luft, according to Redman, used an acid condensing agent at the beginning of the reaction, then washed out the acid completely and added a basic condensing agent. Redman stated that Baekeland deviated from Luft's process in one step only, namely, that Baekeland added the basic condensing agent at the beginning of the reaction. Replying to this, Baekeland stated<sup>43</sup> that the Luft process involving condensation with strong acids gives products of the permanently fusible or Novolak type; or, by increasing considerably the amount of formaldehyde, produces infusible resins contaminated with products of the Novolak type unsuited for technical purposes. He said that if Luft recommended an alkali or alkali carbonate after the condensation with strong acids had taken place, this was done simply to neutralize any remaining acid difficult to wash out of the material.

<sup>43</sup> L. H. Baekeland, *Ind. Eng. Chem.*, 1916, 8, 563.

Fayolle<sup>44</sup> employed sulphuric acid as a condensing agent and added large quantities of glycerol, pitch and oils to serve as organic extending agents.

A method of preserving wood developed by Bevier<sup>45</sup> consisted in impregnating it at 150-300°F. (66-149°C.) at 100-400 lbs. pressure with a mixture of creosote, formaldehyde and resin. This treatment is followed by a hardening process which may consist in forcing milk of lime or resinate of lime into the wood.

**Cast Resins.** The next worker in this field was Story.<sup>46</sup> The process which he employed consisted in submitting phenol to the action of aqueous formaldehyde at a high temperature for a number of hours until a viscous product was obtained. This could be cast in molds and finally hardened by heating at a tem-

FIG. 57.—Bakelizer. This apparatus is simply a container in which phenol-formaldehyde resins can be heated under pressure. Carbon dioxide or other gas is supplied to the bakelizer to create a pressure of several atmospheres on the resin which is undergoing hardening. Sufficient pressure is applied to counteract the tendency of the resin to become spongy due to the escape of gas when heat is applied. The apparatus has been used experimentally but finds very few commercial applications.

perature below 100°C. A mixture of 150 parts of commercial carbolic acid (95 per cent) and 30 parts of 40 per cent formaldehyde solution was recommended by Story. The reaction vessel was provided with a reflux condenser. At the end of about 4½ hours at 100°C. with continual rapid agitation the solution becomes cloudy. The heating is continued usually for a period of about 8 hours giving a product of somewhat creamy appearance. This is transferred to an open vessel and concentrated rapidly, the temperature being raised above 100°C. to drive off as much water as possible. The product should now become clear especially if the preliminary boiling has not been continued for too long a period. The viscosity of the product gradually increases and the temperature should be lowered below 100°C. after a time. Eventually a solid substance is obtained. This is hard, tough, and transparent and is a good electrical insulator. Opaque products result when the preliminary boiling is continued for a longer time, or when the concentration is conducted at a temperature below 100°C.

When shaped articles are desired the product in liquid form is poured into heated

<sup>45</sup> A. Bevier, U. S. P. 681,032, Aug. 20, 1901; British P. 10,297, 1900; *J.S.C.I.*, 1900, 19, 827.

<sup>46</sup> W. H. Story, British P. 8,875, 1905; *J.S.C.I.*, 1906, 23, 195; Belgian P. 210,965, 1908. Austrian P. 30,844, 1905. German P. 173,990, 1905. French P. 353,995, 1905; *J.S.C.I.*, 1905, 24, 1081. See also French addn. 9,861, 1908; *J.S.C.I.*, 1909, 28, 381.

molds and these are placed in a drying oven at about 80°C. until solidification occurs. The mass shrinks sufficiently in drying to allow the article to be withdrawn from the mold. When a very light-colored product is desired it is best, according to Story, to exclude air and light. The addition of small quantities of fatty oils, such as castor, almond, olive or rape oils, is conducive to opacity. When air is excluded during the boiling operation and fatty oil is added, the product is a white substance, which, Story stated, has the appearance of ivory or bone. The plastic material may be colored with pigments or dyes, and a black product resembling ebonite is made by the addition of pitch, lampblack, asphaltum or aniline black.

While the resin is still in a viscous state it may be dissolved in alcohol, acetone or benzene to yield a solution adapted for use as a varnish. If the solution is not too concentrated the coating will dry to a hard surface by mere exposure to the air, or may be heated to harden the resin and remove all trace of solvent. Such a varnish, according to Story, may be used for waterproofing paper and fabrics or may be employed as a vehicle in the preparation of paints. Once the resin has become hard and dry it is quite insoluble in all solvents and unattacked by acids or alkalis in the cold. Fuming nitric acid, however, disintegrates it.

The procedure of manufacture may be modified by adding the carbolic acid in small quantities from time to time to an excess of hot formaldehyde solution, or the formaldehyde solution may be added in small quantities to hot carbolic acid. A third modification consists in passing formaldehyde vapor through hot carbolic acid.

**Resins from Phenol Alcohols.** From the phenol alcohols, hard translucent resins usable as substitutes for copal, amber and shellac were produced through a process involving heating under diminished pressure.<sup>47</sup> The phenol alcohol prepared by condensing formaldehyde with phenol, cresol or menthol, is placed in a capacious receiver, melted under vacuum and heating continued at a temperature near the boiling point of the phenol alcohol so long as any water is given off. With the alcohol from cresol, the heating is continued until the mass solidifies. Solidification does not occur in the case of the o- or p-phenol alcohol,  $\text{HO}-\text{C}_6\text{H}_4-\text{CH}_2\text{OH}$ , but the end of the reaction is indicated by the appearance of copious white fumes and on cooling a hard transparent resinous mass is obtained. Saligenin yields a homogeneous, pale yellow resin resembling gum-lac, insoluble in alcohol, melting at a temperature somewhat above 110°C., and scratched by the finger nail with difficulty. The resin from p-hydroxybenzyl alcohol is somewhat similar in properties. It melts above 115°C. and has a specific gravity of 1.06. These products are soluble in hot caustic soda and are precipitated from solution by acids. Oil of camphor and terpineol are solvents. The alcohol derived from p-cresol when heated in this manner forms a transparent resin which is quite hard and heavier than water. When heated above 200°C. it softens but does not melt, and at about 300°C., begins to carbonize. The resins obtained from the cresyl alcohols are comparable in some respects with the copals.

Phenol alcohols can be condensed with certain other organic bodies to give resins of value in the plastic field. The condensation of phenol alcohols with aniline, nitrocresol, phthalic anhydride and dihydroxydiphenylmethane yields resinous masses of utility.<sup>48</sup> Condensation can be accomplished by the action of alkaline agents or by organic or mineral acids, or under the influence of heat alone, *in vacuo* or under pressure, exposed to the air or in a current of an inert gas. When condensation is carried out under pressure by heat alone, the phenol alcohol is mixed

<sup>47</sup> British P. 15,517, 1905, to Fabrique de produits de chimie organique de Laire; *J.S.C.I.*, 1906, 25, 857. German P. 159,282, 1905; French P. 350,180, 1904; *J.S.C.I.*, 1905, 24, 1244.

<sup>48</sup> Belgian P. 192,590, 1906, to Fabrique de produits de chimie organique de Laire. See also French P. 361,539, 1905; *J.S.C.I.*, 1906, 25, 939.

with the other reactant and heated in an oil bath until water vapor is evolved. The source of external heat is then removed as the temperature of the mixture rises on account of the heat of the reaction. Two successive condensations have been observed, (1) a condensation taking place while raising the temperature to about 100°C. yielding resins which are soluble in alcohol and the other usual organic solvents; and (2) a condensation taking place at a temperature above 100°C., the exact point varying with the reactants. A further evolution of water vapor occurs and a hard transparent mass more or less colored is obtained. Polymerization occurs and the solubility is dependent upon the degree of this change, the product becoming less soluble in alcohol as polymerization advances. The end product of all these condensation reactions is insoluble in alcohol.

A mixture consisting of 10 parts of phenol alcohol, 1 part of dihydroxydiphenylmethane, 15 parts of water and 3 parts of hydrochloric acid is agitated for several hours. The reaction mass is washed with water until neutral, unreacted raw materials are removed by distillation with steam, and the product is heated *in vacuo* or in the open air until the evolution of steam ceases. The product on cooling forms a transparent mass soluble in alcohol and fusing at about 100°C. Approximately the same result is obtained by dissolving 10 parts of phenol alcohol and 1 part of dihydroxydiphenylmethane in alcohol, heating *in vacuo* at a temperature of about 100°C. until the evolution of vapor ceases.

Starting with formaldehyde one procedure is as follows: 10 parts of phenol, 5-10 parts of aqueous formaldehyde (40 per cent), and 10 parts of hydrochloric acid (15 per cent) are stirred for some time and the excess of hydrochloric acid and phenol removed by washing. A plastic mass remains which is heated in the open air or under the pressure of an inert gas until, on cooling, solidification takes place rapidly. In general this requires heating for one-half hour at about 140°C. The resulting hard resin resembles amber, has a color varying from yellow to brilliant brown, and has nearly the transparency of glass. The resin is soluble in methyl and ethyl alcohols and also in caustic alkali.

A resin having approximately the same physical properties is made by carrying out the condensation in the foregoing manner, with the exception that an alkaline catalyst is used in place of hydrochloric acid. Phenol may be replaced by a homologue. For example, cresol may be condensed with formaldehyde in the presence of caustic potash.

On heating to 100°C. 2 parts of nitroresol and 10 parts of phenol alcohol dissolved in alcohol, maintaining the temperature at this point until vapor is no longer expelled and then removing the excess phenol alcohol by distillation, a resin is obtained which fuses below 100°C. and exhibits good resistance to shock. Hydrochloric acid may be added as a catalyst.

A procedure for condensing phenol alcohol with aniline consists in heating a mixture of 50 parts of phenol alcohol and 10 parts of aniline in an oil bath at about 100°C. until the evolution of water vapor ceases and test samples upon cooling show the resin to have acquired the desired consistency. The resin, which can be molded, is transparent, is scratched with difficulty by the finger nail and possesses a slight solubility in alcohol and alkalies. A more soluble resin is made by using a salt of aniline, for example the salicylate. This is condensed with the phenol alcohol by heating.

Four parts of phenol alcohol and 1 part of phthalic anhydride are dissolved in alcohol, which is removed by distillation, and the residue is heated in an oil bath at 100°C. until the evolution of water appears to cease and a test sample solidifies to a transparent resin soluble in alcohol. By prolonging the heating the product

becomes insoluble in alcohol. The following classes of substances are listed as having the power of modifying the properties of phenol alcohols in some cases presumably as a result of condensation: aldehydes, ketones, polybasic acids and anhydrides, phenols, amines and hydrocarbons.

A thorough study of the synthesis of phenol alcohols was made by Auwers<sup>40</sup> in 1907. He confirmed the results reported by previous workers that only ortho and para derivatives are obtained by the condensation of phenols and formaldehyde. His observations showed that, especially with the homologues of phenol, the para compound could be formed selectively by using the strongest alkalies such as caustic soda. Thus from p-xenol, caustic soda and formaldehyde at room temperature, the para compound was obtained in practically quantitative yield. m-Xylenol, formaldehyde and slaked lime heated carefully to 50°C. gave a fairly good yield of o-hydroxymesityl alcohol. Frequently, however, oily and resinous bodies were formed which appear to be derivatives of dihydroxydiphenylmethane, particularly with some phenols.

**Various Condensing Agents.** A "formic-aldehyde compound" was described by Stephan<sup>41</sup> in 1904 which was made in a way that may be regarded as a precursor of present methods of making phenol-formaldehyde resins. Stephan used an alkaline condensing agent (caustic potash) and formaldehyde in excess of equimolecular proportions. By heating 2 parts by weight of phenol, 1 part of caustic potash solution (40°Bé.) and 4 parts of aqueous formaldehyde to 100°C. in an autoclave, reaction occurred violently with a rise of pressure of 0.5 atmosphere. When this reaction subsided the composition was heated on a steam bath until a voluminous white powder separated on the addition of acid. The product, insoluble in water but soluble in alkali, was said to be of value as a disinfectant.

Helm<sup>42</sup> condensed aldehydes and phenols by means of amines or ammonium salts to make resinous bodies. He used 290 parts of naphthol dissolved in 150 parts of a 40 per cent solution of formaldehyde, and added 95 parts of aniline. After the reaction is over the resinous product is washed and may be used, he stated, as a substitute for gum-lac. Instead of 290 parts of naphthol, 190 parts of phenol may be used, heating to effect condensation if desired, with the formation of similar substitutes for resins or gums.

In 1903 Henschke<sup>43</sup> found that an alkaline solution of phenol, heated with formaldehyde at 100°C. in an autoclave, lost its phenolic odor. Acids precipitated from the reaction mixture a bulky, pale yellow powder, insoluble in water or chloroform, but soluble in alcohol, acetone, dilute sodium hydroxide and ammonia. It decomposed on heating or on boiling its alkaline solution. A powder intended for medicinal use was made by Sternberg<sup>44</sup> by treating wood tar with formaldehyde and hydrochloric acid. A condensation product of phenol or thymol with formaldehyde was prepared by Hildebrandt,<sup>45</sup> using hydrochloric acid as a condensing agent. Dürkopf,<sup>46</sup> Merck<sup>47</sup> and Hock<sup>47</sup> obtained condensation products of tannin and formaldehyde or hexamethylenetetramine.

Lebach<sup>48</sup> produced rapid-hardening phenol-formaldehyde resinous compositions by using inorganic or organic acid chlorides, sulphuric acid esters, aluminum

chloride and various salts as condensing agents. One procedure involves the heating of 1000 parts each of phenol and aqueous 40 per cent formaldehyde with 100 parts of crystallized sodium sulphite. A light-yellow, viscous liquid is formed which is cooled and treated with 600 parts of wheat starch and 200 parts of 20 per cent sulphuric acid. The mass is heated in a mold at 85°C. for 1-2 hours. The product is a hard lustrous insoluble article.

In another case Lebach heated phenol, formaldehyde and sodium sulphite in proportions as given above for a short time, then distilled off 500-600 parts and mixed the residual liquid with 600 parts of wheat starch. To this were added in the cold 150 parts of a mixture of 1 part sulphuric acid to 9 parts of glycerol and the product was heated in molds to 60°C. for half an hour. This gave a solid article of brilliant surface, free from pores, which could be washed with soda solution or exposed to ammonia fumes to neutralize the acid. Subsequent heating to about 100°C. improved the hardness and strength of the product. Instead of the mixture of sulphuric acid and glycerol, 10 parts of a 25 per cent aqueous solution of sodium bisulphite or 5 parts of benzoyl chloride could be used.

To avoid the problem of removal of traces of acid from the resin, Lebach proposed the use of acid salts. Small quantities of ferric chloride produce a soluble resin. Large quantities tend to promote a violent reaction and yield an insoluble resin. Ammonium chloride, sulphate and nitrate, potassium carbonate and bisulphate, and sodium sulphite were also recommended. In an example of their use, 500 parts of commercial cresol from which o-cresol has been removed, 370 parts formaldehyde and 10 parts of ammonium chloride are heated to boiling until a colorless oil separates. When separation ceases a vigorous current of steam is blown through the mass to remove excess cresol and any uncombined aldehyde. After heating for about an hour a further addition of 10 parts of ammonium chloride is made and the heating continued until a white, brittle, resinous mass is obtained on cooling a sample. The product is washed thoroughly with hot water.

In another case 500 parts of cresol, 400 parts of formaldehyde and 20 parts of sal ammoniac are heated at water-bath temperature until separation of an oil is complete, then toluene vapor is blown through the batch. In this way formaldehyde and cresol are removed. When the mass becomes cloudy the introduction of toluene vapor is stopped. On removal of traces of toluene, *in vacuo* for example, a clear transparent resin soluble in alcohol results. Various fillers may be added to the resinous composition and the aqueous formaldehyde may be replaced by hexamethylenetetramine.<sup>90</sup>

Grognot<sup>91</sup> attempted to minimize the violence of the reaction between phenol and formaldehyde in the presence of hydrochloric acid by adding glycerol. He first treated glycerol with formaldehyde in the presence of hydrochloric acid, and subsequently condensed the reaction product with phenol. A recommended procedure is the following: 2 parts by weight each of glycerol and formaldehyde are mixed and 0.3-0.4 part of hydrochloric acid (21-22°Bé.) are added. The mixture is heated until a slight ebullition occurs and reaction progresses spontaneously thereafter without external heating. When the reaction has subsided, heat may be applied for 1 or 2 hours, avoiding vigorous boiling. The mixture is cooled to 80°C. and 2 parts by weight of phenol crystals are added. Reaction takes place without further heating and is accompanied by a slight ebullition. The resin, which separates as a viscous oily layer, is washed and dried, then heated to about 150°C. until a test sample shows a hard, brilliant bead. Volatile liquids<sup>92</sup> can be added to moderate the reaction.

# Chapter 14

## Phenol-Aldehyde Resins

### II. Theoretical. Constitution.

Many large industries have resulted from the observation that phenol-formaldehyde products can undergo chemical transformation under the stress of temperature and pressure to form insoluble and infusible materials. Moreover, the nature of the chemical reactions involved has been the subject of considerable study, and, accordingly, the literature abounds in speculations and controversies concerning the structures of the substances involved, and the mechanism of the changes taking place. A number of noteworthy experimental investigations have been carried out, but the data which have been obtained serve largely to demonstrate the complexity of the problem rather than to provide its solution. A large number of compounds have been isolated from the condensation product. These are generally assumed to be intermediates in the resin formation, and theories concerning the structures of the resinoids<sup>1</sup> are arrived at through a consideration of the possible fates of these intermediates. Often the speculative structures are at variance with analytical data, chemical properties or physico-chemical evidence.

It has become well established that a change of catalyst may produce variation in the ease with which individual intermediates can be isolated. Therefore it appears that the course of the resin-forming reaction is determined at least in part by the nature of the catalyst. At any rate, a different set of isolable intermediates is obtained through the use of *acidic* condensing agents from the compounds produced in the presence of *alkali*. Likewise the properties of the less highly condensed resins depend upon the catalyst employed, and it is reasonable to suppose that such divergences have their source in structural differences.

Since there is no universally accepted scheme of descriptive names for the phenol-formaldehyde condensation products, their subdivision into (1) soluble-fusible resins and (2) insoluble-infusible resins is regarded as sufficiently comprehensive for the purposes of this chapter. The products of the initial stages of phenol-formaldehyde resin formation fall into the former class, and the final stage into the latter. This scheme is not intended to ignore the possible existence of a soluble infusible resin, or an insoluble fusible resin, but these are types which are seldom encountered. The term saliretin is generally accepted for those substances obtained by the action of heat on individual phenol alcohols. A typical phenol alcohol is o-hydroxybenzyl alcohol (*saligenin*),

<sup>1</sup> The term "resinoid" is here used in the sense of a synthetic resinous substance in the stage of highest stability and infusibility. This is the meaning of the designation in many of Baekeland's publications. See M. Koebner, "Brit. Plastics Year Book," 1934, 67, for general discussion of related topics.

The saliretins are the result of intermolecular condensation with elimination of the elements of water, and belong to the soluble fusible class (the Növolaks of Baeke-land).

The main line of approach to the many problems associated with resin formation is an attempt to carry out a particular condensation under as mild conditions as possible, to eliminate the unchanged reactants, to isolate chemical compounds from the condensed residue, and if possible to identify them. Mention should be made of the two chief methods which have been employed for the isolation of these compounds, viz., solvent extraction and distillation. To a limited extent degradation products of the final resins have been obtained and examined. It is relatively simple to study substances produced by condensing formaldehyde with a phenol which gives a minimum number of initial products. To elaborate this scheme: phenol, m-cresol and sym-m-xlenol are the three phenols most prone to resin formation. They are alike in the respect that each has three positions available for attack in the first stage of resin formation (two positions ortho and one position para to the hydroxyl group, the meta position being unreactive). In short each can give rise to different condensations depending upon the point of attack. On the other hand, o- and p-cresol have only two positions in their molecule free for attack. Likewise, 2,3-, 2,5- and 3,4-xlenols have two vulnerable positions. Phenols which have only a single reactive hydrogen in the benzene ring (2,4- and 2,6-xlenols) would be expected to do one of two things: either to combine with formaldehyde in equimolecular proportions or else to condense in the ratio of two molecules of phenol for each molecule of formaldehyde, to give a diphenylolmethane of the type  $\text{HOC}_6\text{H}_4\text{—CH}_2\text{—C}_6\text{H}_4\text{OH}$ . Further condensation involving aromatic hydrogens would not be expected if the positions ortho and para to the hydroxyl are blocked by alkyl groups. However, when phenol homologues having more than one reactive position are condensed with formaldehyde, not only are isomeric compounds obtained in the initial step, but alternative modes of subsequent condensation and polymerization are possible.

#### PHENOL ALCOHOLS

Reference has been made to two of the types of derivatives from phenol-formaldehyde condensation, viz., phenol alcohols and diphenylolmethanes. The former class is obtained when condensation occurs in alkaline solution, while the latter are usually isolated from an acid medium. The phenol alcohols are unstable to heat, which converts them into soluble resins.<sup>2</sup> Acetic anhydride removes the elements of water from saligenin<sup>3</sup> forming products representing various stages of dehydration. In this way a resin analyzing for carbon, 77.7, and for hydrogen, 5.8 per cent was obtained. This corresponds to the loss of 7 water molecules from 8 molecules of saligenin. The isolation of phenol alcohols from the condensation of phenol and formaldehyde was accomplished by Manasse<sup>4</sup> and Lederer.<sup>5</sup> Auwers and co-workers<sup>6</sup> found that concentrated alkali favored the formation of p-hydroxybenzyl alcohols, and that milder alkalies such as lime produced a certain amount of diphenylolmethane derivatives. The possibility of the formation of di-alcohols was also considered. Thus, Ullmann and Brittner<sup>7</sup> prepared 2,6-dimethylol-p-cresol

by reacting 108 g. p-cresol dissolved in 200 cc. water containing 50 g. sodium hydroxide with 215 g. of a 35 per cent formaldehyde solution. After 4 days, the mass had become crystalline. Upon acidification of a solution of this sodium 2,6-dimethylol-p-cresylate with dilute acetic acid, a 91 per cent yield of 2,6-dimethylol-p-cresol was obtained. The recrystallized product melted at 135°C. Similar compounds from o-cresol received mention by Granger<sup>8</sup> who was able to prepare a definite di-alcohol of o-cresol and who also postulated the existence of di- and tri-alcohols of phenol and m-cresol in the syrupy products obtained from them. The xylenols form mono-alcohols with considerable ease,<sup>9</sup> but they evidently are reluctant to take up their full quota of formaldehyde molecules to form poly-alcohols. Steric hindrance may be the cause of the unreactivity which appears when the first  $-\text{CH}_2\text{OH}$  group has been introduced into a xyleneol. Amann and Fonrobert recommend the isolation of definite phenol alcohols prior to conversion into synthetic resins.<sup>10</sup> Megson<sup>11</sup> represents the formation of branched-chain resin compounds from poly-alcohols by the following scheme.

It is of interest to note that hydroxybenzyl alcohols, and resins derived from them, are formed in reactions other than phenol-formaldehyde condensations. Gsell<sup>12</sup> undertook to condense phenol and chloroform in alkaline solution in order to prepare hydroxybenzaldehydes. He found that the latter were unstable under the experimental conditions, and underwent the Cannizzaro reaction ( $2\text{RCHO} \rightarrow \text{RCOOH} + \text{RCH}_2\text{OH}$ ). The hydroxybenzyl alcohols which were formed were converted into plastic masses by the alkali. A similar experience was recorded by

Shoesmith.<sup>13</sup> He attempted to isolate the hydrolysis products of *o*-chlorotolyl carbonate  $\text{CO}(\text{OC}_6\text{H}_4\text{CH}_2\text{Cl})_2$  in acid solution. Instead of hydroxybenzyl alcohol, he obtained a resin. Pauly and Schanz,<sup>14</sup> investigating reactions which would produce substituted hydroxybenzyl alcohols, avoided resinification by using (as the condensing agent) a quantity of potassium carbonate just sufficient to produce bluing of litmus. In the case of chloral and phenol, a 60-70 per cent yield of *p*-hydroxyphenyltrichloromethylcarbinol,  $\text{HOC}_6\text{H}_4\text{CH}(\text{OH})\text{CCl}_3$ , was secured. The time required was 6 weeks.

#### DIARYLMETHANES

Preparation of compounds of the type  $\text{HOC}_6\text{H}_4\text{CHRC}_6\text{H}_4\text{OH}$  by condensing aldehydes with phenols in the presence of acids is sometimes referred to as the Baeyer reaction.<sup>15</sup> As an example of this reaction, 100 g. of acetaldehyde are mixed with 856 g. of phenol and a few drops of concentrated hydrochloric acid are added. Crystallization of the reaction product from phenol gives a substance said to be *p*-diphenylolethane plus a molecule of phenol of crystallization. When this molecule of phenol is removed by distillation, crystalline diphenylolethane is obtained (m.p. 122.9°C.). A large number of homologues of diphenylolethane have been made<sup>16</sup> in this manner.

Trautenberg<sup>17</sup> called attention to the fact that not only 4,4'-diphenylolmethane (m.p. 158°C.) and the 2,4' isomer (m.p. 115°) were isolable from the condensation of phenol and formaldehyde, but that there was also formed a certain amount of a triphenylolmethane (aurin). It has been noted<sup>18</sup> that a yellow-gray resin precipitated when equal quantities of phenol and 35 per cent formaldehyde solution were heated in a quartz flask for 50-60 hours on a water bath under reflux. The mixture was filtered. From the resin were isolated crystals of 4,4'-dihydroxydiphenylmethane, and from the filtrate, 2,4'-dihydroxydiphenylmethane. A small quantity of saligenin was also obtained from the resin.<sup>19</sup>

Substituted phenols have been observed to react with formaldehyde in acid solution to yield diphenylolmethane derivatives. Thus, *p*-nitrophenol yielded a mixture of (5,2- $\text{O}_2\text{N}(\text{HO})\text{C}_6\text{H}_3$ )<sub>2</sub>CH<sub>2</sub> and 6-nitrobenzo-1,3-dioxin.<sup>20</sup>

Although an acid medium is usually desirable for the preparation of diphenylolmethane and its homologues, certain phenolic compounds form diarylmethanes both by acid and by alkaline condensation. This is true of the naphthols.<sup>21</sup> Polyvalent phenols give not only diarylmethanes but also triarylmethanes without the use of acid catalysts.

A number of observations have been made which throw light upon the chemistry

of the diphenylmethanes. Gomberg<sup>22</sup> made monohydroxydiphenylmethanes by the action of benzyl chloride on phenol in the presence of zinc dust, copper-bronze or aluminum chloride. In alkaline media, phenylbenzyl ether was produced. Huston<sup>23</sup> obtained similar results by heating a solution of benzyl alcohol and phenol in light petroleum, using aluminum chloride as a catalyst. An interesting tendency towards the formation of condensed rings is indicated by the reaction between phenol and benzaldehyde in acid media:<sup>24</sup>

Condensation of p-nitrobenzaldehyde with 2 molecules of  $\beta$ -naphthol gave ms-[4-nitrophenyl]-dinaphthopyran.<sup>25</sup> Formaldehyde combined with 2 molecules of  $\beta$ -naphthol in the presence of a trace of hydrochloric acid, yielding dinaphthopyran.<sup>26</sup> The initial product from furfural and phenol in acid solution is  $\text{C}_6\text{H}_5\text{OCH}(\text{OH})\text{C}_6\text{H}_5\text{OH}$ .<sup>27</sup> Robinson and Walker<sup>28</sup> obtained benzopyrylium salts by condensing a reactive phenol with an unsaturated aldehyde or ketone in acid solution and in the presence of an oxidizing agent. Good yields of 7-hydroxy-2,4-diphenylbenzopyrylium chloride were obtained from resorcinol and benzylideneacetophenone with chloranil:

#### THEORIES OF CONSTITUTION OF PHENOL-FORMALDEHYDE PRODUCTS

Baekeland<sup>29</sup> viewed the phenol-formaldehyde reaction as a condensation and polymerization which took place in three stages, the resinous materials formed being termed respectively *initial condensation product A*, *intermediate condensation product B* and *final condensation product C*. These designations have now come into universal use. Under ordinary conditions, A may be liquid, pasty or solid. B is an insoluble solid which swells upon addition of acetone, phenol or terpeneol. B can be melted (or, rather, softened by heat) a limited number of times before

it is converted into C, which is infusible and indifferent to all solvents. The nature of these materials renders it excessively difficult to obtain experimental evidence concerning their structures. The problem of purification increases with the complexity of the substances, until, in the case of Bakelite C, we have a material which can neither be dissolved, distilled nor melted. The determination of molecular weight, for instance, is not a simple matter.

In the study reported in 1909, Baekeland<sup>30</sup> compared the products of three different reactions: (1) saligenin plus phenol (2) phenol plus formaldehyde with an alkaline catalyst and (3) phenol plus formaldehyde with an acid catalyst. Saligenin reacted with phenol to give a soluble fusible resin identical with the material made by acid condensation. However, a reaction corresponding to an alkaline condensation of phenol with formaldehyde gave a different product. Thus saligenin was heated with varying amounts of formaldehyde and it was found that at least one-sixth of a molecular proportion of the latter was necessary to produce stage C. With smaller amounts of formaldehyde the product was always one which was attacked by solvents. Using sealed tubes and a small amount of base as catalyst, elimination of a certain amount of water marked stage A. Elimination of more water resulted in stage B, but the transformation of the latter into stage C involved no further splitting of water and no change in volume, suggesting polymerization as the probable explanation of the change from B to C.

Baekeland made certain tentative explanations of these phenomena. Assuming that saligenin condensed with itself through the intermolecular reaction of phenolic and aliphatic hydroxyl groups, and in view of the fact that one-sixth of a molecular proportion of formaldehyde must be added to convert saligenin into the final resin, stage C was considered to be made up of units such as the following:

An advantage possessed by this type of structure is that it leaves open the possibility of varying the number of saligenin units to be condensed with a single molecule of formaldehyde. Thus, Lebach<sup>31</sup> obtained a substance formulated as

The intermediate products which Baekeland prepared by acid condensation were more amenable to inspection than those obtained through the use of alkali. It was noted that when 15 mols of phenol were heated with 14 mols of formaldehyde in the presence of a small amount of hydrochloric acid a soluble fusible variety of resinous mass (Novolak) was obtained. In acid solutions, an excess of phenol over that indicated in the proportions above quoted was beneficial to the formation of Novolaks. On the other hand, even when an excess of phenol was employed, alkaline condensations did not produce the Novolak variety of resin, but infusible insoluble products. Whenever an excess of phenol was used, either in

<sup>30</sup> L. H. Baekeland, *Ind. Eng. Chem.*, 1909, 1, 158.

<sup>31</sup> H. Lebach, *Z. angew. Chem.*, 1909, 22, 1599.

acid or alkaline solution, free phenol was present in the final product. Analysis of the resin from acid condensation verified its identity with that obtained by heating saligenin with phenol. Each of the resins had the constitution  $C_{20}H_{28}O_4$ .

In contradistinction to Baekeland's "ether-linkage formation" hypothesis, Raschig<sup>22</sup> suggested that the phenol alcohols which are formed initially may react in two ways:—

- (1) with more phenol to give diphenylolmethanes

- (2) with themselves to form alcohols of diphenylolmethanes

When the reactants in equation (1) are phenol or o- or p-hydroxybenzyl alcohol, three isomeric dihydroxydiphenylmethanes should be produced. As noted earlier in this chapter, two of these isomers, 2,4'- and 4,4'-dihydroxydiphenylmethane, have been isolated by various workers from actual resin preparations. The 2,2'- derivative has been crystallized only in the form of an ether or ester. Raschig stated that soluble fusible resins arise when less than one molecular proportion of formaldehyde per molecule of phenol is used, while the insoluble products are formed when the formaldehyde is in excess of this amount usually to the extent of about 10-20 per cent. In the former case the relative molecular proportions would favor the production of diphenylolmethanes. If saligenins were formed these would condense with the excess of phenol to give the diarylmethane. Baekeland has shown<sup>23</sup> that diphenylolmethanes are converted into insoluble infusible resins by heating with paraformaldehyde. In the latter case, i.e., when formaldehyde exceeds one molecular equivalent, Raschig postulated that the resins are mixtures of great complexity, the products of the earlier stages of their formation being diarylmethanes and phenol alcohols. These two classes of compounds can condense with one another as well as with more phenol. The ultimate material would consist not only of molecules of great size, but of molecules of various sizes, e.g.,

A. Two molecules of the mono-alcohols of diphenylolmethane combine with loss of two molecular proportions of water.

B. With double the proportion of formaldehyde and assuming that a di-alcohol of phenylolmethane is present as one stage in the reaction, the product becomes (III).

<sup>22</sup> F. Raschig, *Z. angew. Chem.*, 1912, 25, 1945; *Chem. Abs.*, 1913, 7, 887.

<sup>23</sup> L. H. Baekeland, *Ind. Eng. Chem.*, 1913, 5, 507.

(III).

(IV)

C. This may condense further with the elimination of water to give Raschig's representation of Bakelite (IV).

Formulas II, III and IV are obviously only some of the many that can be conceived possible by similar reactions. After the publication of Raschig's work and views, Baekeland suggested the possibility that the resins may be composed of material which is still more complex than the compounds described by Raschig, and that, if the latter bodies were present, "together with an endless variety of other chemical individuals," their relative importance was not understood. Redman, Weith and Brock<sup>84</sup> state that Raschig's formulations are not in agreement with actual analyses.

Raschig also demonstrated that the action of heat alone on either o- or p-saligenin could produce saliretins but with a mixture of the two, and a basic catalyst, an insoluble infusible material was formed. He concluded from this evidence that both saligenins were necessary to produce Bakelite types of resin. Baekeland<sup>85</sup> investigated this point still further as it was contrary to the views he had expressed in his first paper. He found that if maintained at 160°C. for about 6 hours, o- and p-saligenins alone or in admixture with either ammonia or caustic soda as catalyst did not produce insoluble and infusible resins but only brittle infusible bodies which were immediately soluble in caustic soda. However, with an added amount of paraform (as little as 5 per cent) the product was of great hardness and was unattacked by caustic soda.

Neither Raschig nor Baekeland at that time undertook to assign any definite reason for the polymerization to a hard insoluble body. It is inconceivable that the resin would become insoluble simply on account of the complexity of its component molecules. Moreover molecular size alone is no criterion of insolubility (*cf.* starch and protein).

Wohl and Mylo<sup>86</sup> reasoned that p-saligenin by changing to its tautomeric form would lose water and thus furnish a quinoid compound which will then polymerize under the experimental conditions employed.

<sup>84</sup> L. V. Redman, A. J. Weith and F. P. Brock, *Ind. Eng. Chem.*, 1914, 6, 3.

<sup>85</sup> L. H. Baekeland, *loc. cit.*

<sup>86</sup> A. Wohl and B. Mylo, *Ber.*, 1912, 45, 2046

A similar reasoning would apply to o-saligenin. Only a small amount of evidence or support for these views has since been put forward. Sugimoto<sup>27</sup> states that Bakelite has an empirical formula  $C_7H_6O$  agreeing with that of the quinoid compound mentioned above. A similar view was supported by Connerade,<sup>28</sup> who condensed benzyl chloride with trioxymethylene in acetic acid at 50°C. using sulphuric acid as the catalyst. He obtained the 2,4'- and 2,2'-dichloromethyl-diphenylmethanes which were converted into the corresponding iodo compounds. Treatment of the latter with silver nitrate to replace the iodine by a nitrate group was accompanied by polymerization. Hence subsequent hydrolysis gave rise to a polymer of the di-alcohol of diphenylmethane. Connerade's formulation of the reaction requires the presence of quinoid forms:

Driver<sup>29</sup> states that the resin formed during the preparation of hydroxy-benzaldehydes by the Reimer-Tiemann synthesis,<sup>30</sup> is not due to condensation of the aldehydes with phenols in alkaline media. In acid media, however, they do combine with phenol in equimolecular proportions to give complex alkali-soluble red resins of empirical formula  $C_{13}H_{10}O_2$ . The resins are assumed to be polymers of the quinoid anhydride of 2,4'-dihydroxybenzhydrol.

In order to determine the kinetics of the reaction, Jablonower<sup>31</sup> studied the increase in density when phenol and formaldehyde reacted in the presence of ammonia. His results supported Baekeland in that the initial stage was shown to be one of condensation, followed by polymerization.

Van Voorhout<sup>32</sup> investigated the effects of varying the catalyst. He identified o- and p-saligenin as intermediate products under alkaline conditions. In acid media 4,4'-diphenylolmethane was formed. His results indicated that the stronger the base the stronger its condensing power. Bakelite was postulated as mainly polymerized diphenylolmethane associated with traces of unchanged material in solid solution.

Beatty<sup>33</sup> condensed diphenylolpropane with aqueous formaldehyde under alkaline conditions and suggested that the reaction proceeded as follows:—the first stage as in equation (1) to form an alcohol while further condensation occurs as in equation (2) with the elimination of water.

Herzog and Kreidl,<sup>44</sup> emphasizing the fact that unsaturation was a marked feature of compounds which are known to polymerize, suggested the presence of the grouping  $-\text{CO}-\text{CH}=\text{CH}-$  in Bakelite A and B to account for their properties. A quinonoid rearrangement of Raschig's formulas was written so as to include this grouping.

In 1925 Baekeland and Bender<sup>45</sup> reviewed previous work and recorded some experimental data in support of a new hypothesis in which the role of ethers was still an important one. When hydrochloric acid was employed as the catalyst they distinguished three chemical steps in the condensation of formaldehyde and phenol. (1) Two molecular proportions of phenol combine with one of formaldehyde to give an unsymmetrical ether, p-hydroxyphenylphenoxymethane, which they regard as being the chief constituent of the fusible soluble resin. The steps in the formation of this ether may be represented by:

Further rearrangement of the ether yields dihydroxydiphenylmethane (diphenylol-

methane). (2) Condensation of the ether with another molecule of formaldehyde, union occurring at the methylene group. This gives rise to Stage B.

(3) Polymerization of the unsaturated compounds obtained in the second step is believed to mark a gradual passage to Stage C.

When acetaldehyde or acetone replaces formaldehyde, the  $\text{CH}_2$  grouping of the product obtained in the first step then becomes  $\text{CH}_3\text{CH}$  or  $(\text{CH}_3)_2\text{C}$ , respectively. Such fusible soluble resins can combine further<sup>46</sup> with formaldehyde to reach Stage C. The possible reaction for the derivative from acetone, for example, is:

Alkaline condensation of formaldehyde with phenol is postulated as taking place through an intermediary ether which subsequently rearranges to p-saligenin.

Baekeland and Bender treated phenol with n-butyraldehyde (in the presence of dry hydrogen chloride) with the expectation that the speed of reaction would be sufficiently slow to enable them to isolate large yields of the intermediaries, thereby obtaining convincing evidence that ether formation was involved in the preparation of phenolic resins. After seven days the mass had become a jelly with much crystalline material in suspension. On separation the latter was proved to be  $\alpha,\alpha,\text{p},\text{p}'$ -dihydroxydiphenylbutane (m.p.  $136^\circ\text{C}.$ ) (yield 38 per cent). The resinous residue was found to have the same empirical formula, and similar molecular weight, but only one free hydroxyl group could be detected by titration. When the resin was heated at  $260\text{--}310^\circ\text{C}.$  under reduced pressure (22 mm.) 79 per cent distilled over. This distillate solidified and proved to be identical with the crystalline material melting at  $136^\circ\text{C}.$  It was considered that the resin was phenoxy-p-hydroxyphenylbutane and that heating rearranged it to the diarylbutane.<sup>47</sup>

Baekeland and Bender's views are such as to suggest that any phenol will condense with formaldehyde to a resin so long as it can yield first a diphenylol-methane. The highly polymerizable substance is formed by combination of formaldehyde with the methylene grouping joining the two nuclei. It has been shown<sup>48</sup> that 2,6-dimethylphenol (a "single-position" phenol) will yield a Novolak resin, though a considerable amount of hydrochloric acid as catalyst is necessary. The dioxynolmethane formed must have the structure,

<sup>46</sup> Cf. J. Scheiber and K. Sändig, "Artificial Resins," English Translation by E. Fyleman, Isaac Pitman & Sons, Ltd.; London, 1931, 97.

<sup>47</sup> Similar rearrangements have often been observed. See M. Gomberg and R. L. Jickling, *J.A.C.S.*, 1915, 37, 2575. J. B. Niederl and E. A. Storch, *J.A.C.S.*, 1933, 55, 284. R. A. Smith, *J.A.C.S.*, 1934, 56, 717.

<sup>48</sup> F. S. Granger, *Ind. Eng. Chem.*, 1932, 24, 446.

No further reaction with formaldehyde occurs, the reason assigned being that no active position remains open to substitution.<sup>49</sup> Mesitol<sup>50</sup> (2,4,6-trimethylphenol) reacts with formaldehyde to give a crystalline substance (m.p. 186-187°C.) formulated as:

According to Megson, the dixylenolmethanes are converted gradually into resins, and he therefore believes dihydroxyarylmethanes to be true resin intermediates. Megson objected to Baekeland and Bender's idea that resinoid C is a polymer of the ether type

on the grounds that rate of resinification (conversion to resinoid C) is so largely governed by the nature and positions of the substituents in the phenyl groups. He therefore subscribed to the theory that polyalcohols and branched-chain structures were involved.

The idea that di- and tri-alcohols may be formed was stressed by Amann and Fonrobert<sup>51</sup> who suggested the following scheme:

Thus, the resin was thought to consist of a long chain of hydroxybenzyl groups.

Blumfeldt<sup>52</sup> proposed that an "idealized" formula for Bakelite C be given by the structure (b) shown on next page. Such a representation could result from the condensation of two long molecules of the type (a). (For a further discussion of this work in relation to the structure of resins in general, see Chapter 4.) This would indicate a hydrocarbon of very compact structure and low hydrogen content, somewhat similar to what has been postulated for graphite,<sup>53</sup> but while the latter is of course insoluble it has marked crystalline features with a cleavage plane, a factor influencing its use as a lubricant. No such property has been discovered in Bakelite C. Analytical results do not agree with such a small oxygen content.

<sup>49</sup> Carbon atoms which are ortho or para to the phenolic group and to which no substituting groups are attached are designated active positions.

<sup>50</sup> N. J. L. Megson, *J.S.C.I.*, 1933, 52, 421T.

<sup>52</sup> A. E. Blumfeldt, *Chem.-Ztg.*, 1929, 53, 493; 1931, 55, 551; *Chem. Abs.*, 1929, 23, 5179; 1932, 26, 609.

<sup>53</sup> L. Wallerstein (U. S. P. 1,442,372, Jan. 16, 1923; *Chem. Abs.*, 1923, 17, 1115) has found that the carbon derived from charred phenol-formaldehyde resin is highly absorptive, and is comparable with coals produced by the carbonization of animal or vegetable matter.

It is to be noted that Blumfeldt utilized only ortho-substituted rings in this case and he did this specifically for he regarded the Novolaks as being, in their idealized form, chains made up in a manner requiring para substitution.

According to Blumfeldt, these ideas explain the following four points concerning stage C:

- (1) Its remarkable stability at 300°C.
- (2) When dry distilled the elements of water are not lost.
- (3) Its polymerization is exothermic.
- (4) It is very slowly attacked by alkali.

Koebner<sup>54</sup> criticized this formula on the grounds that it does not permit of a

<sup>54</sup> M. Koebner, *Chem.-Ztg.*, 1930, 54, 619; *Brit. Plastics*, 1930, 2, 197; *Plastics and Molded Products*, 1930, 6, 653; *Chem. Abs.*, 1930, 24, 8039.

sufficient number of hydroxyl groups in the material to accord with the formation of sodium salts soluble in alcoholic soda, which are however insoluble in water. Its formation also necessitates the elimination of more water than actually occurs during the reaction. He regards the combination of phenol with formaldehyde as being more complex than that of the cresols and places the latter in the order of complexity of their condensations as *m*- < *o*- < *p*-. This is rather unexpected, as *m*-cresol belongs to the three-position phenols and in *p*-cresol the two substituting free positions are symmetrically placed. One would therefore expect the order to be:—condensation of *m*- much more complex than that of *o*- which is more than that of *p*-cresol. Koebner<sup>55</sup> recognized the importance of the formation of homologues and isomers of the resin intermediates. He demonstrated that 2 mols of *p*-cresol united with 1 mol of formaldehyde at 150°C. without a catalyst to form a Novolak, and that the yield of isolable dicresylmethane derivative was fairly good. However, in an experiment in which formaldehyde was condensed with phenol instead of *p*-cresol, the presence of isomers was bothersome and the yield of the diphenylmethane was small. Koebner favored the view that Novolaks are long chain molecules of the type  $R(CH_2R)_nCH_2R$ . The true Novolak would be a mixture of compounds with different values of *n*.

Koebner also showed that, accompanying the formation of a dicresylmethane from *p*-cresol and formaldehyde, there was produced a smaller amount of a crystal line substance (m.p. 215°C.) for which the analysis indicated the structure:

This three-ring compound was also made by condensing *p*-cresol-dialcohol (2,6-dimethylol-4-methylphenol) with *p*-cresol in acid solution. Hence its structure was ascertained. Koebner also prepared and isolated the compounds containing 4, 5, 6 and 7 substituted benzyl groups in a chain.<sup>56</sup> An independent isolation of the three-ring compound (m.p. 214°C.) was described by Morgan, Megson and Drummond.<sup>57</sup> Megson<sup>58</sup> reported that along with the two-ring and three-ring compounds a series of amorphous substances can be made from *p*-cresol and formaldehyde. For these he suggested the representation,

An acid of the formula

has been prepared<sup>80</sup> by condensing p-cresoldialcohol with 2 mols of p-cresolcarboxylic acid in the presence of concentrated hydrochloric acid.

Pollak and Riesenfeld<sup>80</sup> subscribed to the theory that Novolaks consist of a chain of seven phenol molecules condensed by six formaldehyde molecules when six molecules of water are eliminated. Two phenol molecules are removed when the product is treated with water or caustic soda, consequently they rejected any ring formulations for a Novolak, and suggested<sup>81</sup>

The exact configuration was not determined, and the resinous character was attributed to the presence of isomeric compounds. It was assumed that the resin was made up entirely of substances of the same molecular weight. The molecular weight determinations indicated a value of about 523 for the Novolaks, whereas a value of 730 is demanded by the theory of seven molecules of phenol combining with six of formaldehyde. The use of the Grignard reagent in pyridine solution (Zerewitinoff Method) gave evidence of the presence of 13 hydroxyl groupings per molecule as measured by the volume of methane evolved.

Hugel and Vincent<sup>82</sup> made a series of phenol-formaldehyde condensations in which they varied the concentration of both formaldehyde and catalyst. From these experiments they could detect no essential difference between acid and alkaline catalyzed products but concluded that hardening was due to the addition of an excess of formaldehyde above that required for the fusible resins. Koebner<sup>83</sup> also determined the molecular weights<sup>84</sup> of a series of Novolaks formed by acidic condensations in which the proportions of formaldehyde varied from 1 to 7 mols per 10 mols of p-cresol and found that the values so obtained increased progressively with the amount of formaldehyde used.

TABLE 26.—Condensations of Formaldehyde with 10 Mols. *p*-Cresol.

Gram-mol. CH <sub>2</sub> O	Yield of Resin		Mol. Wt. Found
	Found g.	Calcd. g.	
1 . . . . .	180	250	229
2 . . . . .	335	306	256
3 . . . . .	470	412	291
4 . . . . .	590	518	334
5 . . . . .	710	624	371
6 . . . . .	810	730	437
7 . . . . .	870	836	638

This is fairly conclusive evidence that, using *p*-cresol, Novolaks consist of chains of varying lengths, and of alternate cresol and methylene linkages.

If the Novolaks do consist of chains of substituted benzyl groups, the question arises as to which isomers are most likely to be involved. Megson and Drummond<sup>65</sup> quote evidence that 2,4'-dihydroxydiphenylmethane is the resin-forming intermediate. When phenol and formaldehyde condense in the presence of hydrochloric acid, both 2,4'- and 4,4'-dihydroxydiphenylmethane are obtained. Heating the mixture causes formation of resin and decrease in the quantity of 2,4'-isomer. This view is in agreement with the observation of Driver (already mentioned) that 2,4'-dihydroxybenzhydrol readily yields a resin.<sup>66</sup>

Morgan and Megson<sup>67</sup> propound further that any polynuclear compound from phenol and formaldehyde possesses free positions in internal rings at which condensation to form macromolecular structures is possible.

From this point of view, Novolaks may be regarded as substances of the general formula  $\text{HOR}''(\text{CH}_2\text{R}'''\text{OH})_x\text{CH}_2\text{R}'''\text{OH}$ . The resols, or initial products of alkaline

condensation are mono- or poly-alcohols. Resitols (B stage resins) are macromolecules which are only partly united by methylene groups. Resites (C stage) are branched-chain macromolecules.

This theory is, of course, very much at variance with the view expressed by Baekeland and Bender (*vide supra*). A more recent version<sup>66</sup> of Baekeland's idea indicates the manner by which final polymerization might take place.

The same investigators heated phenol-formaldehyde resin in an autoclave with 10 or 15 per cent sodium hydroxide solution at 300°C. for several hours. Such hydrolyses gave higher phenols than those which were used as starting materials. It was found also that a considerable amount of hydrogen was evolved. The net result could be indicated in the following manner:

Degradation experiments evidently give interesting results, but have not yet solved the problem of resin constitution. Moehle<sup>67</sup> found that the hydrogenation of phenol-aldehyde resins at 440°C and 125 atmospheres yielded phenols and light oils.

#### PHENOL-HEXAMETHYLENETETRAMINE CONDENSATIONS

The replacement of formaldehyde by other aldehydes (or even by ketones) in the preparation of resins has no very drastic effect upon the nature of the intermediates or of the resin. The differences which do manifest themselves are such as can be easily explained, or possibly anticipated, from considerations of the properties of the particular aldehydic reactant used. When hexamethylenetetramine (hexamine) however is employed the difference is more marked.

Various workers<sup>70</sup> noted the formation of hexamethylenetetramine from ammonia and formaldehyde. Lösekann<sup>71</sup> has suggested  $\text{N}(\text{CH}_2\text{---N=CH}_2)_3$  as its constitution. Duden and Scharff<sup>72</sup> expressed the view that ammonia and formaldehyde (or its polymer), interacting with liberation of heat, yield as the first stage a product formulated as (I) the complete reaction resulting in hexamine (III) possibly through the intermediate stage (II), viz:—

<sup>66</sup> I. Allen, V. E. Meharg and J. H. Schmidt, *Ind. Eng. Chem.*, 1934, 26, 634

<sup>67</sup> E. Moehle, German P. 370,270, 1931, to A.-G. für Steinkohleverflüssigung und Steinkohleveredelung; *Chem. Abs.*, 1933, 27, 2592.

<sup>71</sup> G. Lösekann, *Chem.-Ztg.*, 1890, 14, 1409; *J. C. S.*, 1892, 62, 423.

<sup>72</sup> P. Duden and M. Scharff, *Ann.*, 1895, 288, 218, 938.

This representation of hexamethylenetetramine is commonly but not universally accepted. X-Ray considerations tend, however, to support this acceptance.<sup>73</sup>

When ammonia is used as the catalyst in phenolic condensations it is assumed that hexamine is first formed. In such cases, the ammonia can be recovered almost quantitatively during dehydration of the resin product. The efficacy of hexamine in speeding up the initial condensation was found by Holmes and Megson<sup>74</sup> to be practically equal to that of ammonia in m-cresol-formaldehyde reactions. The possibility of employing hexamine in the production of phenolic resins early attracted attention<sup>75</sup> (see also Chapters 13, 15 and 16). The value of introducing dry hexamethylenetetramine as a hardening agent (rather than mixtures which would form the substance) was recognized by Aylsworth.<sup>76</sup>

Under mild conditions three molecular proportions of phenol combine with one of hexamine to form a definite compound.<sup>77</sup> A crystalline substance of composition  $\text{C}_6\text{H}_{12}\text{N}_4 \cdot \text{C}_6\text{H}_6\text{O}$  (m.p.  $176^\circ\text{C}.$ ) has also been isolated.<sup>78</sup> Harvey and Baekeland used various homologues of phenol and found that less than three molecules would combine with one of hexamine giving compounds with ill-defined melting points and strong resin-forming tendencies.  $\beta$ -Naphthol, heated with hexamethylenetetramine in acetic acid, yielded 2,2'-dihydroxy-1-naphthylidene-1'-naphthylmethylamine,

$\alpha$ -Naphthol, under similar conditions gave sym-di- $\alpha$ -naphthoxy-dimethylamine. With p-nitrophenol, hexamethylenetetramine formed an addition compound,

The stability of the phenol-hexamine bodies has been studied by Pummerer and Hofmann.<sup>80</sup> In water or benzene the compounds reverted to their components. Union of phenol and hexamine is effected by mixing them in the presence of a little alcohol. Lebach<sup>81</sup> and also Sugimoto<sup>82</sup> noted that hexamine triphenol evolved ammonia when heated to yield an insoluble infusible mass similar to Bakelite C.

Redman, Weith and Brock<sup>83</sup> found that hexamethylenetetramine was decomposed completely by boiling in dilute aqueous hydrochloric acid, though alkalis had no effect. When the compound of hexamine and phenol was heated, methylamine as well as ammonia was given off. Dry heating at 175°C. for 1 hour resulted in a resin attacked both by solvents and dilute acid. By adding phenol so that the molecular proportion of formaldehyde to phenol was 7 to 6, no longer were methylamines evolved, but only ammonia. This indicated a complete combination of the formaldehyde with the phenol. When phenol was added beyond the 7:6 ratio, the excess could always be separated on completion of the reaction and the resin was believed to be identical with that resulting from the 7:6 ratio. Amino-saligino-saligenin,  $\text{HOC}_6\text{H}_4\text{OCH}_2\text{C}_6\text{H}_4\text{CH}_2\text{NII}_2$ , was isolated as an intermediate, but at the end of the reaction no such substances could have been present, as all of the nitrogen was accounted for in ammonia evolved. It was suggested that a long saligino-saligenin chain constituted the initial soluble resin (Novolak). Analysis agreed with the formulation of  $\text{C}_6\text{H}_5\text{OCH}_2(\text{C}_6\text{H}_4\text{OCH}_2)_n\text{C}_6\text{H}_4\text{OH}$ . Transformation into an infusible insoluble resin required condensation with additional active methylenes. Another conclusion which was reached from a study of the hexamine resins was that their superior light-fastness indicated a possible freedom from hydroxyl groups, a conclusion supported by the fact that very prolonged treatment with caustic soda was necessary before signs of attack could be observed.

Sato and Sekine<sup>84</sup> found that phenol-formaldehyde condensations catalyzed by ammonia could be fractionated into three components by virtue of their different solubilities. Megson and Drummond<sup>85</sup> observed this same property in m-cresol condensations catalyzed by caustic soda and these fractions also had different heat hardening rates. Duff and Bills<sup>86</sup> reported that when hexamine and salicylic acid were heated in aqueous solution, 3- and 5-aldehydosalicylic acids were obtained (and separated by their differing solubilities in benzene) instead of the expected methylalsalicylic acids. m- and p-Hydroxybenzoic acids gave only amorphous products. Shono<sup>87</sup> isolated a light yellow amorphous powder, whose analysis indicated  $\text{C}_{14}\text{H}_{18}\text{O}_2\text{N}$ , from a phenol-formaldehyde condensation catalyzed by a large amount of ammonia. Other compounds<sup>88</sup> isolated were 2,2'- and 4,4'-dihydroxydibenzylamines melting at 168°C. and 137-138°C., respectively. At higher condensation temperatures (140°C.) a compound,  $\text{C}_{14}\text{H}_{18}\text{O}_2\text{N}$ , stated to be  $\omega$ -amino-o-tolyl-o-hydroxybenzyl ether was formed.

Marotta and Alessandrini<sup>89</sup> also studied the reaction between phenols and hexamine in acetic acid solution and they suggested that hexamine is first oxidized to trihydroxytrimethylamine, which in turn condenses with the phenol.

Phenol, resorcinol, phloroglucinol and naphthols all gave products which were difficult to purify and which became plastic masses when warmed or exposed to air. Naphthols gave bases, by reactions formulated as:

Resins made from phenol and hexamethylenetetramine<sup>80</sup> were found to be infusible whenever the methylene to phenol ratio in the resin was greater than 0.5 to 1. Therefore the only fusible intermediates are dinuclear. A different result was obtained by starting with saligenin, in which case polynuclear fusible resins were obtained, along with infusible resins which contained at least 11 molecules. It was suggested that the resins consist of mixtures of open chain as well as ring systems.

The effects of amines other than hexamethylenetetramine in causing reaction of phenols with formaldehyde are discussed in Chapter 16. The mechanism of these catalyses presumably varies from case to case and it is difficult to make any generalizations. The statement can be made, however, that crystalline products which may be intermediates have often been encountered. Thus, from monophenols and formaldehyde in the presence of dimethylamine, compounds of the type  $\text{o-HOC}_6\text{H}_4\text{CH}_2\text{N}(\text{CH}_3)_2$  were obtained.<sup>81</sup> Phloroglucinol condensed with formaldehyde and dimethylamine hydrochloride to yield  $(\text{HO})_3\text{C}_6\text{H}_2\text{N}(\text{CH}_3)_2\cdot\text{HCl}$  and  $(\text{HO})_3\text{C}_6\text{H}[\text{CH}_2\text{N}(\text{CH}_3)_2\cdot\text{HCl}]_2$ . These hydrochlorides gave resins when treated with alkali. Aminophenols and aldehydes gave substituted methyleneaminophenols.<sup>82</sup>

#### PHYSICO-CHEMICAL STUDIES OF PHENOL-FORMALDEHYDE RESINS

Sato and Sekine<sup>83</sup> have called attention to the amphoteric nature of phenol-formaldehyde resins. When the alkaline condensation products of phenol and formaldehyde are washed till neutral to litmus, and then dissolved in acetone, the addition of a comparatively large amount of alkali is necessary to render the solution alkaline to phenolphthalein, yet more than an equivalent of acid is necessary to turn the same solution acid to congo red. A characteristic dark yellow substance is formed when copper sulphate is introduced into the condensation product, but there is no blue coloration when ammonia is added. The yellow color was discharged by lactic acid. Copper carbonate, however, gave a brown product unaffected by lactic acid. The amphoteric nature of these resins is considered to be due to the presence of both aromatic and aliphatic hydroxyl groups. The investigators deduce that the resin molecules should combine with compounds containing an aliphatic hydroxyl group. Sato<sup>84</sup> confirmed this by preparing insoluble resinous material from the condensation of the oily reaction product of equimolecular parts of phenol and formaldehyde, with malic, lactic or glycollic acid, butyl alcohol, glycerol, cholesterol and hexoses.

Shono<sup>85</sup> recorded 40 metallic salts which would react with phenol resins in alcohol solution. The chlorides of cobalt, iron, vanadium, selenium, titanium, ruthenium and tungsten, uranium nitrate, various chloroaurates and chloroplatinates gave characteristic colors. These color reactions served as a means of differentiating this type of synthetic resin and natural resins. The action of condensation products derived from polyhydric phenols and formaldehyde on aqueous solu-

tions of metallic salts was studied by Adams and Holmes.<sup>96</sup> The resins exhibited pronounced and selective adsorptive properties for a large number of cations (e.g.,  $\text{Al}^{+++}$ ,  $\text{Ca}^{++}$ ,  $\text{As}^{+++}$ ,  $\text{Pb}^{++}$ ,  $\text{Sn}^{++}$  and  $\text{V}^{++}$ ). As a result of their experiments the investigators recommended the use of such resins as pyrocatechol-formaldehyde, resorcinol-formaldehyde, pyrogallol-formaldehyde and quebracho tannin-formaldehyde for the purification of water.

The behavior of alcoholic suspensions of resins under the influence of an electric field was investigated by Barthélemy.<sup>97</sup> Alkaline-catalyzed resins were found to migrate to the cathode, and acid-catalyzed ones to the anode. He regarded them therefore as ionic micelles having the constitution:

The growth of colloidal aggregates presumably occurs through the ionic nature of these particles. Ripper,<sup>99</sup> comparing Barthélemy's formulation with the structures mentioned by Raschig<sup>100</sup> and Herzog,<sup>101</sup> suggests that in the final resin the value

Possible structures existing within ionic micelles

of  $n$  is greater than 4, since structures as shown above probably would not display colloidal properties. Nagel and Baumann<sup>102</sup> find that the reaction mechanism for the hardening of phenol-formaldehyde resins involves the formation of large molecular aggregates without the elimination of any water (with shellac a little is formed). These investigators were unable to find evidence for any chemical reaction taking place during hardening. The sizes of colloidal resin particles<sup>103</sup> range from the smallest which can be detected by means of the ultramicroscope to the largest which are present in partial suspensions.

It is known that resin-forming reactions are facilitated by stirring.<sup>104</sup> Freundlich and Kroch<sup>105</sup> have shown that stirring coagulates copper oxide sols, indicating that orientation and aggregation can be accomplished by this means. According

to Ostwald<sup>106</sup> the effect is due to potential differences set up between the stirrer and the colloid system. Exposure of Bakelite to a concentrated electric field was reported to have catalyzed hardening of the resin. The effect was assumed to be due to changes in the energy content of the particles.<sup>107</sup> Jablonower<sup>108</sup> found that the density of a phenol-formaldehyde condensation catalyzed by ammonia, increased steadily with the time of heating and the proportion of catalyst used.

While the advanced stages of the phenol-formaldehyde reaction involve the aggregation of colloids, the initial syrups are merely mixtures of crystalline substances which necessarily lower each other's melting points, and which are supercooled liquids. This was demonstrated by Drummond<sup>109</sup> through the use of viscosity measurements. Initial syrups obtained by alkaline condensation of phenol with formaldehyde obeyed Slotte's law for the variation of viscosity with temperature:  $\eta = K/t^n$ , where  $t$  is in degrees Fahrenheit. The law does not hold for colloids.<sup>110</sup> This observation of Drummond that the logarithm of the viscosity of the initial resin varied linearly with temperature has been confirmed.<sup>111</sup> Warren, Newbound and Bell<sup>112</sup> suggested that automatic control of condensations might well be based on viscosity measurements.

Novak and Cech<sup>113</sup> decided that since intermediate stages in the formation of resins from the reaction of phenol with formaldehyde were difficult to isolate, it might be possible to study them by determining the refractive index, the viscosity in alcohol and the bromine value (by Koppeschaar's Method) of the filtrate which remained after precipitating an acetic acid solution of the resin with water. They studied various types of condensation, including (1) uncatalyzed, (2) catalyzed by ammonia, (3) catalyzed by caustic soda. Condensation phenomena were manifested by decrease in the bromine value and in the refractive index of the aqueous layer, while polymerization was indicated by increase in refractive index of the resin layer and partly by increased viscosity.

Schmid and de Senarcens<sup>114</sup> followed the change in refractive index (using yellow helium light of 5876Å) during the conversion of resin A to resin C in the presence of varying amounts of caustic soda ranging from 1.07 to 2.66 per cent at 100-140°C. The values they obtained for any one set of conditions increased rapidly at first and then more slowly until the maximum was reached. Increases in the concentration of caustic soda lowered the maximum value of the refractive index. The data indicated that polymerization proceeded at the same time as did condensation and that polymerization was not affected by the alkali.

Sugimoto and Kasai<sup>115</sup> investigated the absorption spectra of phenol-formaldehyde products prepared without catalysts, and a band was found only in the ultraviolet. Using ammonia as catalyst there appeared bands which were traced to the presence of a decomposition product of hexamnetriphenol. The red color formed in Bakelite in the course of time was shown to be due to a triphenyl-methane dye (aurin).

Boer, Houwink and Custers<sup>116</sup> studied the absorption curve of a phenol-formaldehyde resin and found that it was similar to that of phenol but approximated that of cresol in that it was displaced towards the red. This was considered to be a striking confirmation that the structure is  $(\text{CH}_2\text{C}_6\text{H}_4\text{OH})_x$ . Molecular refraction measurements had increased values as condensation between phenol and formaldehyde proceeded, an increase related quantitatively to the absorption displacement towards the red.

Stäger<sup>117</sup> prepared resins by reacting formaldehyde in the presence of ammonia with three different sources of phenols, viz., pure phenol, cresol and mixtures of phenol with cresol. Eleven specimens of resin in all were examined. Their specific gravity at 20°C. ranged from 1.18 to 1.24. The resins had melting points of about 59-67°C. and bromine absorption of 0.32-0.53 g. per g. of resin. Cementing values towards steel were obtained with reference to the time of hardening and many electrical tests were carried out, the investigator concluding that products derived from formaldehyde and pure phenol have definite polar characteristics. The cresol derivatives have comparatively high molecular weight and are non-polar. Stäger noted also<sup>118</sup> that when the resins were heated at 100°C. for considerable periods of time, thus forming stage C, the volatile material obtained consisted chiefly of water and phenols.

#### SUMMARY

In the preceding pages the reactions of formaldehyde and phenols have been discussed and mention has been made of aldehydes other than the simple formaldehyde. Various views as to the mechanism of these condensations have been examined and a certain amount of general agreement has been found among them. Yet the significance of the fact that phenol-formaldehyde condensation products polymerize under definite conditions of time, temperature and pressure has not been fully elucidated. The main facts established are these:—

1. The initial reaction of phenols and formaldehyde results in the formation of compounds of the alcohol type or of the diarylmethane type or a combination of both.
2. These compounds react further to form extended molecules which may be regarded as joined substituted benzyl groups possessing oxygen or carbon linkages.
3. The chains or *branchiae* particularly in the presence of some slight excess of formaldehyde and a basic catalyst can be transformed irreversibly into insoluble, infusible material, most probably by polymeric change.

## Chapter 15

### Phenol-Aldehyde Resins

#### III. Commercial Processes

During the first decade of the present century activity greatly increased in the study of phenol-aldehyde resins and their applications as substitutes for shellac and other resins in both varnishes and plastic compositions. In the latter part of that decade, Baekeland began an investigation which brought forth a modification of these resins by improving the methods of hardening under heat and pressure so that rigid molded articles could be very readily obtained. From his investigations came the commercial development of the molding composition and product known in its various forms as Bakelite. A great variety of applications have been made of these phenol-formaldehyde resins or resinoids ranging from bottle closures to telephone hand-sets; from table tops to artificial amber. The range of uses also embraces such articles as molded cases and parts for cameras, clocks and precision instruments, armatures and commutators for dynamos and motors, automobile parts, electrical equipment, grinding wheels, toilet seats, serving trays, soda-fountain counters, scale pans, golf clubs and containers of many kinds. The commercial success of this material has been a powerful stimulant to the development of the industry of synthetic plastics.

To a notable extent the applications of phenol-formaldehyde resins in the plastics field have been spectacular and during the period of commercial development and expansion they have therefore been particularly before the public eye. Such varied applications as radio apparatus, pencil barrels, ash trays and other articles constantly in evidence give some indication as to the importance of these resins for which accurate consumption data are not available.<sup>1</sup>

In the United States, the production of molding compositions was practically restricted to one corporation, the rights of manufacture having been closely retained by the owners of the principal patents.<sup>2</sup> Since the expiration of some of the original patents (1926), a number of other manufacturers have become firmly established in the United States.

In the past, the molder requiring such compositions purchased his raw material at a price roughly representing one-half the cost of the molded article, that is, the costs of the composition and of labor were about equal. With increasing competition the prices of molding compositions gradually decreased. Simultaneously

<sup>1</sup> Accurate production figures for phenol-formaldehyde resins have been largely withheld. However, it has been estimated that in the United States in 1921 the production was between 2000 and 3000 tons; in 1928, it was about 10,000 tons. [A. Marcus, *Chem. Age (London)*, 1929, 20, 538]. According to L. V. Redman (*Chem. Markets*, 1929, 24, 481), in the decade 1919-1929 there was a tenfold volume increase.

<sup>2</sup> During the early stages of L. H. Baekeland's commercial development, J. W. Aylsworth and L. V. Redman independently began the manufacture of the related products, Condensite and Redmanol respectively, and in 1916 a controversy took place between Baekeland, Redman (and his associates, A. J. Weith and F. P. Brock) and K. Brown (as Aylsworth's successor), partly over the bearing of Redman's process on Baekeland's inventions. (See *Ind. Eng. Chem.* 1911, 3, 439, 518; 1914, 6, 3, 167, 263; 1916, 8, 177, 473, 568, 1077, 1171; 1917, 9, 207.) After much litigation a consolidation of these competitive interests was effected (see *Chem. Met. Eng.* 1922, 25, 279; 1923, 26, 996, 1184) and the products Bakelite, Condensite and Redmanol, were placed under the control of the Bakelite Corporation.

with the expiration of the original patents, a number of molders started and have continued manufacturing their own materials. This private manufacture<sup>3</sup> has been based largely on the need for smaller quantities of resins which are better suited for particular purposes.

In view of the publicity given phenol-formaldehyde resins and their uses in a number of striking ways, there has been a possibly unwarranted amount of activity among research workers in adding to, modifying, and transforming them. It has even been thought advisable by Stone<sup>4</sup> to familiarize chemistry students with this field by including an experiment on the preparation of a resin from phenol and paraformaldehyde in their training. The result of this extensive interest has been a large amount of published work whose study presents no small task to one desirous of becoming familiar with the field. An attempt is made here to review all of the available published material, and it is believed that in the following pages a very complete survey will be found. However, space limitations prevent extended review of all references and the present objective has been rather to indicate the keynote of any particular investigation and to give those wishing to pursue the subject further guidance to the original literature.

If more of the zeal which has been put into the study of modifying phenol-formaldehyde resins or of making additions to them for the purpose of accomplishing only a minor change in physical characteristics had been applied to such problems as control in manufacture, acceleration of the molding operation, production of a pure white molding composition, improvement in the strength and appearance of cold-molded products without greatly adding to their cost, elimination of odor and of the disadvantage of darkening under light, production of more flexible moldings, reduction of trouble and time required for casting, formation of castings which will not shrink on cooling, or other problems mentioned by Spencer and Murray,<sup>5</sup> it is safe to say that a greater measure of progress would have been made in the field of resinous plastics.

The condensation products of phenols and aldehydes include a wide range of substances but comparatively few of these are resinous. Of these, a still smaller number are worth considering as practical substitutes for natural resins or for use in molding compositions. Phenol itself and m- and p-cresol yield useful resins with formaldehyde but the corresponding compound of o-cresol is practically useless in thermosetting molding compositions and it must be separated with great care from crude cresol. Higher homologues of phenol produce increasing proportions of inert, non-resin-forming or crystalline bodies as the molecular weight increases.

Many terms have been used to describe the resinous condensation products of phenols and formaldehyde<sup>6</sup> so that much confusion exists. In the present discussion the various names urged by different investigators have been largely omitted from the text; the longer terms, soluble fusible resin and insoluble infusible resin, have been preferred for the sake of clarity.

<sup>3</sup> For a discussion of the plant, labor and materials required in the manufacture of phenol-formaldehyde resins, see W. McHutchison, *Industrial Chemist*, 1934, 10, 383.

<sup>4</sup> C. H. Stone, *J. Chem. Ed.*, 1930, 7, 1663.

<sup>5</sup> D. A. Spencer and H. D. Murray, *J.S.C.I.*, 1927, 46, 637

<sup>6</sup> The terms "resol," "resitol," "resite" and "novolak" are often used. A resol is a resin of the type hardenable by heat to a final infusible and insoluble condition but reacted only to the stage where it still melts when heated and is soluble in acetone; this is also known as the A or "treacle" stage. A *resitol* is a resin of the same type as a resol but further reacted to a B stage where it has become infusible, i.e., it does not melt though it softens decidedly on heating, and it is insoluble but swells in acetone. A *resite* is the same heat-hardenable resin but reacted to the final or C stage, characterized by complete insolubility in acetone and infusibility without any material softening upon heating. A *novolak* is a distinctly different type of resinous reaction product in that practically speaking it does not harden upon heating to an insoluble infusible condition but remains soluble and fusible. A general term for phenol condensation products is "phenoplast."

## MANUFACTURING PROCESSES

In the manufacture of phenol-formaldehyde resins or resinoids (see Chapters 1 and 14) either wet or dry processes (so-called) may be used. The former are based on the use of aqueous formaldehyde, and the latter substitute solid aldehydes (paraformaldehyde, hexamethylenetetramine or similar aldehyde-yielding reagents) for the solution. On account of the expense of anhydrous aldehyde, dry processes are generally used only for the preparation of transparent, translucent or opalescent, light-colored cast or turned<sup>7</sup> articles such as cigar and cigarette holders, umbrella handles, dentures, amber substitutes, beads and similar ornamental objects where the cost of raw materials is less vital than with cheaper molding compositions.

In the wet process, the formaldehyde may be introduced all at once, or it may be added in two stages. For convenience, the two-stage processes will be discussed separately from the one-stage processes, although there is no very definite distinction between them.<sup>8</sup> In both cases, the resin is subjected to heat and pressure in the mold in order to convert it into an infusible insoluble product.

**Two-Stage Wet Processes.** These processes, giving reasonably uniform results, have found favor from a manufacturing standpoint and will therefore be discussed first. Resins made by the one-stage wet process can be expected to be slightly cheaper than those made by a two-stage process, especially when the latter requires the use of anhydrous aldehyde.

In the operation of the two-stage wet processes, a fusible, soluble resin is first formed and then dehydrated in the same reaction kettle. These resins are usually brittle and can be ground for mixing with the anhydrous aldehyde hardening agent. Fillers, coloring materials and other ingredients (if desired) are added at this point. It is possible to determine the optimum time<sup>9</sup> at which to stop stage one by the use of physical tests (hardness and fluidity). Methods for carrying out these tests are described in Chapter 69. The product may then be worked up into a form for molding under heat and pressure.<sup>10</sup>

Baekeland<sup>11</sup> obtained products in this way which when molded were similar to hard rubber or ivory, insoluble in alcohol and acetone, and resistant to heat, moisture and most chemical reagents. Phenol or cresol is treated with about an equal volume of commercial formaldehyde solution (this being approximately equivalent to the phenol molecularly) or a slight excess of the formaldehyde may be used. On heating, with or without catalytic bodies, reaction takes place and a heavy oily viscous layer separates from the aqueous solution. The aqueous layer is rejected and the syrupy liquid, which is soluble in alcohol and acetone, may be heated on a steam bath to thicken it slightly and to drive off any remaining water. If the reaction is permitted to proceed further the product may become gelatinous. At this stage the resin is incompletely soluble in alcohol but more readily soluble in acetone. Heating converts it into a heat-resistant body. Various

<sup>7</sup> The term, "turnery" resins; has been used to designate those which are capable of being worked on lathes and similar devices.

<sup>8</sup> It is evident that almost limitless variations from true one-stage to true two-stage processes are possible, depending upon the quantity of aldehyde required for hardening, and that the differentiation between the two types is not a sharp one.

<sup>12</sup> L. H. Baekeland, U. S. P. 942,659, Dec. 7, 1909; *Chem. Abs.*, 1910, 4, 680. This patent, commonly called the "heat and pressure patent," has been involved in litigation; U. S. Dist. Court, Eastern Dist. of New York, *General Bakelite Co. vs. General Insulate Co.* The patent was held valid. Another case involving its validity was won by the General Bakelite Co. against the Brunswick-Balke-Collender Co. Since the expiration of this basic patent a great deal of competition has opened up in the industry.

fillers (asbestos, wood fiber, rubber, zinc oxide, barium sulphate, calcium sulphate, graphite, horn, bone, starch, pumice and many others have been used) and modifying agents, including resins, nitrocellulose and casein, may be added.

*Courtesy Bakelite Corp.*

**FIG. 58.—Laminated Phenol Plastic Tubing Used for High Voltage Detectors on Power Lines.**

On heating under pressure at 110-140°C., a hard compact molded article is obtained in 1-2 hours.<sup>12</sup> Baekeland observed that various catalysts, such as acids<sup>13</sup> or salts, including zinc chloride and calcium chloride, could be used advantageously.

Baekeland<sup>14</sup> prepared a solid partial reaction product of phenol and formaldehyde to which could be added a filler (e.g., wood flour), ground it, molded it

<sup>12</sup> Present practice reduces the molding time considerably.

<sup>13</sup> Acid condensing agents are not looked upon with favor by commercial molders because of possible corrosion of the molds

<sup>14</sup> L. H. Baekeland, U. S. P. 939,966, Nov. 16, 1909; *Chem. Abs.*, 1910, 4, 680.

under pressure, and by heating at 100-200°C., transformed the resin into an insoluble and infusible condensation product. He suggested a great variety of fillers, including asbestos fiber, other fibrous or cellular materials, rubber, casein, lampblack, mica, mineral powder such as zinc oxide or barium sulphate, pigments, dyes, nitrocellulose, abrasive materials, lime, calcium sulphate, graphite, cement, powdered horn, bone, pumice stone, talc, starch and resins. Wood flour, however, is especially useful to retard shrinkage and minimize brittleness.

To produce shaped or molded articles without keeping the material in molds during the entire hardening operation, Baekeland<sup>15</sup> made an initial condensation product from approximately equal volumes of ordinary commercial formalin and phenol or cresol, separated the water and subjected the oily or viscous material to gentle heating to transform it into an intermediate product which was solid at all temperatures. This product is more or less hard when cold but becomes elastic and capable of yielding to pressure when slightly heated, resuming its original shape if the pressure be discontinued. In this form the material is insoluble in alcohol and glycerol but swells in phenol or acetone. These properties are utilized by heating the initial product in molds until the intermediate product is formed, removing the shaped masses from the mold and subjecting them to further heat treatment to bring about hardening, as heat may be applied under these conditions without danger of deformation. By this procedure the molds are quickly available for further work. The molded articles in the intermediate stage of conversion may be hardened by baking at low temperatures in an inert gas at atmospheric or higher pressures. The process enables the formation of large blocks free from gas bubbles or pores.

The discovery of the value of hexamethylenetetramine in the preparation of phenol-formaldehyde products (see Chapter 14) contributed largely to the extensive utilization of phenolic resins. No adequate substitute has yet been found for this almost ideal hardening agent. It acts as a flux, thereby assisting in the formation of shaped articles. Furthermore, it breaks down giving ammonia, which acts as a catalyst, and methylene groups, which are required for the final hardening. A small percentage of hexamethylenetetramine is sufficient to act as a "trigger" in causing additional formaldehyde to react with the soluble resin. Rapid cures are obtained in this manner (see Chapter 26). In Aylsworth's<sup>16</sup> process a phenol resin is first made in which the proportion of formaldehyde is such that the resin is permanently fusible. This may be heated to 215°C. or higher (a temperature of 200°C. is necessary to remove all free and combined water) and consequently it can be completely dehydrated. Dehydration of partial condensation products which become infusible on further heating could not, of course, be carried out in this manner. To form the final infusible product the dehydrated resin is combined with hexamethylenetetramine or paraformaldehyde. One advantage of using hexamethylenetetramine is that the reaction is more nearly anhydrous, ammonia being evolved but no water or formaldehyde as with paraformaldehyde. No counteracting pressure is needed and the ammonia given off may be rendered harmless by an added substance such as an organic acid anhydride. An entirely anhydrous commercial product of this character would be of special value, according to Brown,<sup>17</sup> where products of high dielectric strength are desired.

Another proposal by Aylsworth<sup>18</sup> particularly emphasized forming fusible phenol-formaldehyde resins with the careful exclusion of catalysts. The ingredients (for

<sup>15</sup> L. H. Baekeland, U. S. P. 942,700, Dec. 7, 1909; German P. 237,790, 1908; *Chem. Abs.*, 1910, 4, 680.

<sup>16</sup> J. W. Aylsworth, U. S. P. 1,020,593, March 19, 1912; *J.S.C.I.*, 1912, 31, 399.

<sup>17</sup> K. Brown, *Ind. Eng. Chem.*, 1916, 8, 1172.

<sup>18</sup> J. W. Aylsworth, U. S. P. 1,102,630, July 7, 1914; *J.S.C.I.*, 1914, 33, 931.

example, 1000 parts by weight of phenol and 750 parts of a 35 per cent formaldehyde solution) are heated in a closed vessel at 150-160°C. without a condensing agent. In fact, Aylsworth stated that any impurity which will act as an accelerator or catalytic agent should be eliminated. For this reason iron and lead vessels are not suitable, but well-enameled or tinned iron and tinned copper or nickel have no objectionable action. The phenol or cresol should be carefully refined to eliminate basic metallic impurities as well as mineral acids. Aylsworth<sup>19</sup> also produced a hard infusible material from a resinous fusible condensation product of phenol and formaldehyde (dehydrated and freed from uncombined formaldehyde) and hexamethylenetetramine, the mixture being heated sufficiently at about 95-115°C. to cause reaction. The hexamethylenetetramine is used in a quantity at least sufficient to combine with all the fusible condensation product and free phenol contained in it. The fusible resin may contain 3 mols of phenol to 2 mols of formaldehyde or equivalent, and to it 7.6 to 12 per cent of hexamethylenetetramine is added.

A somewhat more complicated method of preparing molding compositions was also proposed by Aylsworth<sup>20</sup>. A fusible phenol-formaldehyde resin is dissolved in an alkaline solution. The alkali may be the hydroxide of sodium, potassium, barium or calcium. Fibrous fillers are then added. The alkali subsequently is neutralized by addition of an acid. When the alkali is sodium or potassium hydroxide the neutralizing agent may be stearic acid or rosin. If the basic reagent is calcium or barium hydroxide, an acid (sulphuric, oxalic or carbonic) which forms an insoluble compound may be used. The neutralization of the alkali precipitates the resin together with any insoluble salts which may be formed and the composite mass is dried and used for molding purposes. Hexamethylenetetramine may be added to bring about reaction in the mold. Aylsworth mixed 100 parts of resin with milk of lime formed by the hydration of 24 to 28 parts of calcium oxide with 300 to 600 parts of water. The mixing step is continued until the phenolic resin has completely entered into solution, which takes 12-36 hours. The liquid is then thoroughly incorporated with 70 to 300 parts filling material (wood flour, asbestos fiber, cotton flock or powdered mineral material). The mass is exposed to the action of carbon dioxide until the calcium hydroxide has been carbonated. This composition may be dried and molded, or 5 to 16 parts of hexamethylenetetramine may be added prior to molding.

Kendall<sup>21</sup> prepared a liquid mixture of phenol, formaldehyde and water containing dissolved hexamethylenetetramine, in which the formaldehyde is present in sufficient quantity to react with the phenol to form a fusible resin, and the hexamethylenetetramine sufficient to react with the resin to form an infusible product. The mixture is heated to cause reaction and is converted to a fusible resin containing dissolved hexamethylenetetramine but practically no uncombined formaldehyde.

The production of amber-like substances, according to Redman, Weith and Brock,<sup>22</sup> is carried out by first forming an initial product from phenol and formaldehyde without the addition of any condensing agent. Thus, 3 parts of a 40 per cent solution of formaldehyde and 5 parts of phenol are boiled at atmospheric pressure for a period of 60 to 120 hours. A viscous creamy lower layer and a supernatant layer of water practically free from formaldehyde form. Cresol does not require boiling for so long a period, ordinary commercial cresol reacting to

<sup>19</sup> J. W. Aylsworth, U. S. P. 1,020,593, March 19, 1912; *Chem. Abs.*, 1912, 6, 1377. British P. 3,496, 1911; *J.S.C.I.*, 1912, 31, 347. French P. 436,192, 1911; German P. 307,892, 1911.

<sup>21</sup> D. S. Kendall, U. S. P. 1,418,718, Jan. 6, 1922; *Chem. Abs.*, 1922, 16, 2761.

<sup>22</sup> L. V. Redman, A. J. Weith and F. P. Brock, U. S. P. 1,310,087 and 1,310,088, July 15, 1919; *Chem. Abs.*, 1919, 13, 2429. U. S. P. 1,374,526, April 12, 1921; *J.S.C.I.*, 1919, 38, 647A.

the desired extent in 4 to 12 hours and crude cresol in about 2 hours. With pure phenol the reaction may be accelerated by heating under pressure to 125°C. for 12 to 18 hours. After a viscous resinous mass is made in this manner, 2 additional parts of formaldehyde (that is, 2/3 of the original amount of formaldehyde) are stirred into the first reaction product after removing the water layer which separates in the first stage. This addition is made at a temperature of about 100°C. and the mixture is allowed to cool to 60-70°C. Heat is then applied and water is evaporated rapidly, the temperature rising to about 115°C. Some formaldehyde escapes during this operation. Ordinarily the concentration is carried to a point which renders the mix quite viscous but still permits pouring. Boiling should be stopped before the material reaches a gelatinous state. After this concentration operation 3 to 5 per cent of formaldehyde is added to replace loss and the material is poured into molds, where it is allowed to set at a temperature of 50-100°C. When sufficiently firm it is removed from the molds and kept at the same temperature for a period of several weeks or months, depending on the thickness of the molded masses. By mild heating for a protracted period as described, an amber-like product is obtained which is used to make pipestems, cigar holders and similar articles. A finer color and a harder material which may be machined, sandpapered and buffed to better advantage is obtained by exposure to a finishing heat of 125°C. or higher for several days. The color may be varied by introducing dyes, such as auramin for deep amber or methyl violet for amethyst. Oils or waxes in small quantity yield opaque materials and ground mica or fish-scales produce a shimmering effect when included in the resin.

Glaser<sup>23</sup> utilized the waste liquors or distillates from phenol-formaldehyde manufacture for preparing resins suitable for lacquers by treating them with acids or acid salts below 60°C. After some days the resins precipitate.

Filhol<sup>24</sup> heated phenol and formaldehyde in an alkaline medium (sodium carbonate) at 75-80°C. until the viscosity approached that of the upper limit of polymerization and separated the major portion of the aqueous liquid present. The product was then dehydrated and treated with a catalyst (ethylsulphuric acid or other acid ester) and alcohol, and the polymerization continued at a temperature of 70°C. or lower until the desired stage was reached. Such products may be employed as varnishes. Instead of soluble fusible phenol-formaldehyde resins, acetylated derivatives of these resins, prepared by reaction of acetic anhydride on the resin, may be used. The subsequent action of ethylsulphuric acid produces varnishes and plastic materials having practical advantages because of their transparency, plasticity, luster, and facility of working. The acetylated resins also have the property of plasticizing cellulose acetate, being completely miscible with it in acetone solution. Cost is a drawback to their production.

Walker<sup>25</sup> allowed the condensation of more than 1 mol of formaldehyde with 1 mol of phenol to proceed in the presence of alkaline condensing agents, such as alkali sulphate or caustic alkali, to a stage short of precipitation of the resin, viscosity determinations of the reaction mixture being used for control. The resin is precipitated by the addition of sufficient acid to bring the mother liquor to a pH between 3.2 and 7, the actual acidity and viscosities desired being determined for each specific reaction mixture. Such resins are stated to be particularly light colored, permanent to light and air and, when hardened, of high mechanical strength.

A similar process is described by Schmidt<sup>26</sup> who made a preliminary phenol-

<sup>25</sup> E. E. Walker, British P. 259,046, 1925; *Chem. Abs.*, 1927, 21, 3276.

<sup>26</sup> F. Schmidt, U. S. P. 1,978,821, Oct. 30, 1934; *Chem. Abs.*, 1935, 29, 252. German P. 608,469, 1935; *Chem. Abs.*, 1935, 29, 2627.

aldehyde condensation in an alkaline medium and then added enough acid (e.g., succinic) to maintain a  $p_H$  of 2.5-5.5. The entire mass was simultaneously kneaded and hardened by heat until a non-sticky plastic mass resulted.

Weith<sup>27</sup> prepared a soluble fusible resin from phenol and formaldehyde by using the approximate ratio of 7.5 phenol groups to 6 methylene groups, particularly with an acid catalyst. This resin is washed with water until the catalyst is removed and is then dehydrated. After determining the precise phenol:methylene ratio, enough phenol is incorporated with the resin to bring this proportion to between 9 and 12 phenols to 6 methylenes. Formaldehyde is then added, to establish a phenol:methylene ratio of 1:1, and also a basic catalyst, e.g., ammonia. The latter may be employed in the form of hexamethylenetetramine or hexamethylenetetraminetriphenol equivalent to about 0.1 per cent by weight of the dry resin. Such a mixture may be hardened by allowing it to stand at 40°C. in a mold until it becomes a firm jelly, removing it from the mold and completing the hardening in heated kilns. This material may be sawed, cut, ground or worked into a variety of forms.

Water-soluble, non-sticking resins were obtained by Hole<sup>28</sup> by boiling 100 parts phenol and 100 parts 40 per cent forma. le in the presence of 25 parts potas-

sium hydroxide by weight until the desired viscosity is obtained, 30-40 minutes being sufficient to produce a material suitable for most purposes. Cold water is then added (about 72 parts), the product cooled and 2-3 parts of ammonium dichromate and 36 parts of water with sufficient ammonium hydroxide to prevent precipitation are added. Alcohol can be used to decrease the viscosity of the mixture. Other metallic chromates (dissolved, if necessary, in chromic acid) may replace the ammonium salt. Such products may be used in impregnating various materials, for instance, paper pulp to form printing surfaces and matrices,<sup>29</sup> in varnishes and protective coatings and in water-soluble paints which become insoluble on application.

A condensation product which may be shaped in heated molds is made by Menz<sup>30</sup> by boiling phenol and formaldehyde in the presence of both sodium carbonate and sodium bicarbonate and adding acetic acid after boiling to retard the setting. The composition may be colored by dissolving the initial condensed prod-

uct in bone oil or glycerol, adding the coloring matter, and then mixing with another portion of the material to which acetic acid has been added.

Melamid,<sup>31</sup> to form fusible soluble bodies, diluted formaldehyde (60 g. of 30 per cent solution) with an excess of an electrolyte (300-400 g. of 10 per cent sulphuric acid) and added this to phenol (100 g.) at about 40°C. Reaction is complete in 2 hours, after which the excess phenol and water are driven off. The resin melts at about 90°C., is not changed upon being remelted and does not become insoluble.

The solubility, in sodium hydroxide, of the initial condensates of phenol and formaldehyde prepared with alkaline catalysts was utilized by Hiraoka<sup>32</sup> in making a resin for molding. Finely divided resins, softening at 80-90°C., were obtained by adding an excess of water to the sodium hydroxide solutions of the initial condensation products or by neutralizing such solutions with acids. These precipitated resins were converted directly into molding compositions by mixing with wood flour on hot rolls.

Andron<sup>33</sup> made solid resins, partially or entirely convertible to the B state, by dissolving products in the A state in alcoholic alkali, adding benzene, gasoline or other low-boiling solvents and distilling until water and hydrocarbons were removed. In order to produce an odorless phenol-formaldehyde compound, Edwards heats a mixture of 100 gal. cresol, 100 gal. 40 per cent formaldehyde, and 3000 g. caustic soda. Vapors are discharged by an exhaust fan. After a short time a color change occurs, and at this point alcohol is added to arrest the reaction.<sup>34</sup>

**One-Stage Wet Processes.** Processes which are used for making two-stage resins, will, with some slight changes, yield resins of the one-stage type. The principal objection to one-stage operations is the difficulty of securing a uniform product and the minute control which must be exercised. Control of the reaction becomes more and more difficult as water is removed, even though this takes place at low temperature *in vacuo*, and at the end of the dehydration the reaction usually must be promptly checked. In short, the conditions of manufacture must be determined for each specific reaction. The duration of heating is an important factor. Should a batch of one-stage resin show a formaldehyde deficiency, it must be blended with a batch containing an excess, or a calculated amount of additional anhydrous aldehyde has to be added. One-stage resins generally deteriorate in storage more rapidly than the corresponding two-stage resins. Despite these deficiencies, the lower costs of materials will probably make for one-stage resins a more prominent place in the industry.

The essential factor in the preparation of one-stage resins according to McHutchison,<sup>35</sup> is to obtain a compound which contains the requisite amount of formaldehyde for final hardening.<sup>36</sup> This amount is higher in acid than in alkaline condensations. More careful control must be exercised in the manufacture of one-stage resins, because reaction may easily proceed too far and allow the entire charge, which hardens very rapidly once setting has begun, to set in the digester and become too hard to flow out of the bottom outlet, even though pressure is applied.

Six mols of phenol and 7 mols of formaldehyde in condensing with the elimination of 6 mols of water (these being the proportion given by Baekeland<sup>37</sup> for a resin of the saliretin type) would give a yield of resin corresponding to 118

per cent of the weight of phenol, as has been shown by Ballandras.<sup>38</sup> Commercial resins show yields as high as 140 per cent of the phenol which may result from incomplete dehydration or from the presence of large quantities of formaldehyde in excess of the specified proportions. If the product is that suggested by Baekeland and Bender<sup>39</sup> as the principal constituent of phenol resinoids of the A stage,

(formed by the condensation of 2 mols of phenol and 2 mols of formaldehyde with the elimination of 2 mols of water) the resin yield would be 113 per cent of the phenol. These quantities of phenol and formaldehyde, according to Baekeland and Bender, are theoretically necessary to produce a resin of the A stage which, by polymerization, will go over to the infusible insoluble resinoid of the C stage. In practice, however, larger quantities of formaldehyde than this are generally used in the manufacture of one-stage resins.

Further addition of formaldehyde to phenol-formaldehyde products reduces their dark color.<sup>40</sup> For example, 110 parts of phenol, 100 parts of 40 per cent formaldehyde solution and 5 parts of sodium carbonate are heated until all the carbon dioxide is given off. From this product 50 to 60 parts of water are distilled *in vacuo* and the dehydrated resin is mixed with 75 parts of potato starch. One hundred parts of the cooled mixture are then heated with 1 part of concentrated hydrochloric acid and 4 additional parts of formaldehyde solution, after which the mass is placed in molds and heated for about 15 minutes at 60°C. The product is washed with dilute sodium carbonate solution.

Pollak and Mohring<sup>41</sup> made infusible, clear, transparent resins by using more than one mol of formaldehyde with one mol of phenol in the presence of a weak organic acid and added, after separating the resin, enough volatile base to pass slightly beyond the point of neutralization. For example, they boiled 100 g. of phenol, 100 g. of formaldehyde (40 per cent commercial) solution, and 1.9 g. of salicylic acid under a reflux until the mixture became creamy, a period of from 10 to 12 hours. They then added 6.5 cc. of dimethylamine solution (153 g. per liter), continued the boiling for another 3 to 5 minutes and washed the resin several times with distilled water. To each 100 grams of resin dehydrated *in vacuo* at 75°C. are added up to 7 cc. of 1 per cent ammonia solution. The product after further dehydration *in vacuo* is hardened at 75-110°C. with or without pressure, and has a specific gravity of about 1.274-1.287.

To make a permanently fusible phenol-formaldehyde resin it has been proposed to heat 7 mols of formaldehyde and 13 mols of phenol in the presence of 5 mols of ammonia (25 per cent solution) and to distil off the ammonia and water.<sup>42</sup> Another method is to form a condensation product with an excess of formaldehyde in a strongly alkaline solution and near the end of the reaction to add enough phenol to bring the total amount to 2 to 5 times the molecular proportion of formaldehyde.<sup>43</sup> If condensation is carried out under reduced pres-

sure, the concentration of sodium hydroxide catalyst is increased during the process, because of the evaporation of water.<sup>43</sup>

Bia and de Bielize<sup>44</sup> condensed phenols with a large excess of formaldehyde in the presence of such catalysts as magnesium oxide, sodium carbonate, or a mixture of sodium carbonate and sodium metaborate. The reactants are heated for not more than an hour at the boiling point, cooled to about 50°C., the catalyst neutralized, and the mixture allowed to stand. The liquid resinous product is separated, heated to above 100°C. to dehydrate it and finally molded at 90-112°C. A little paraffin may be added to render the substance more elastic. Either translucent or opaque bodies can be obtained by varying the details of the process.

The reaction between phenol homologues (e.g., cresol) and an excess of formaldehyde (40 per cent solution) was found by Cherry<sup>45</sup> to be catalyzed by slaked lime and aniline (1.5) in an amount equivalent to 6 per cent of the total ingredients. It is stated that this combination of catalysts is especially suited to use with the higher phenolic bodies from the standpoint of rapid hardening, mechanical strength and ease of molding. All the formaldehyde is combined (1.1 mols per mol of phenol) but the product previous to hot-molding is fusible and capable of being worked on mixing rolls.

An opaque resin containing water in colloidal dispersion is obtained by heating phenol (1 mol) with an excess of formaldehyde (2.5 mols) and enough alkali to keep the condensation product in solution. The alkali is neutralized with an acid such as chloroacetic, the salt of which liberates acid during the subsequent heating and the solution is concentrated until it gelatinizes. The gel is hardened by heating at about 80°C.<sup>46</sup>

Hessen<sup>47</sup> refluxed equimolecular quantities of phenol or cresol and formaldehyde in the presence of a basic catalyst until separation into layers occurred. After cooling, the resinous layer is separated from the aqueous layer and one-fifth to one-fourth of the quantity of formaldehyde originally used is added. The resin usually dissolves in this quantity of formaldehyde to a clear liquid. This solution is again heated to separation and the preceding process is repeated 2 to 4 times until the final resin is free from phenol. The proportion of catalyst present in the resin, which decreases with each separation of the aqueous layer, can be maintained by adding fractional parts of the original quantity of the same or other catalyst. The basic substance remaining in the final resin is neutralized, salts formed are removed by extraction with water, and the relatively thin liquid resins obtained are dehydrated. The solid clear final resins are soluble in alcohol, acetone, and sodium hydroxide and may be hardened by heating at temperatures above 60°C. The products, because of their freedom from unreacted phenol, are stated to be stable to light. The quantities used may be as follows:

One hundred parts of phenol, 8 parts of 40 per cent formaldehyde solution, and 1 part of anhydrous sodium carbonate by weight. After removing the aqueous layer, 15 parts by weight of formaldehyde solution are added to the resin and the process is continued as described. The excess base in the compound is neutralized with a 5 per cent tartaric acid solution, the resulting salt is washed out with distilled water, and the resinous solution is evaporated until the desired degree of hardness is reached.

emulsion. This emulsion has very little stability and the particles of resin coalesce very quickly to form a coherent resinous substratum with the adsorption of the substances contained in the solution and the occlusion of some of the mother liquor. Purification of this resin by washing is extremely difficult. By keeping it subdivided and dispersed by the action of protective colloids (gum arabic, saponin, tragacanth, dextrin, gelatin, or others) the resin can be hardened by further heating and precipitated as a fine powder. The separate resin particles lose their power of adsorbing substances contained in the solution during the hardening. The following procedure was suggested:

One hundred g. of phenol are boiled under reflux with 110 grams of formaldehyde solution (30 per cent by weight), 150 cc. of 25 per cent sodium chloride solution in which  $2\frac{1}{2}$  g. of gum arabic are dissolved, 50 cc. of 2N sodium hydroxide solution and 25 cc. of 2N ammonia solution. Reaction proceeds with the formation of a milky condensation product and heating is continued until a sand-like precipitation takes place in the hot liquid itself or on the addition of water or acid to a test sample. The powder is separated by filtering after diluting the mixture with water or acid. The resin obtained is of a slightly yellow color, is practically free from all impurities, and can be kept for an indefinite period without changing. Some of the powders are completely soluble in alcohol and alkali.<sup>49</sup> Spitzer<sup>50</sup> proposed to precipitate plastic masses from colloidal solutions of phenol-aldehydes by the addition of a colloid such as urea-formaldehyde hydrosol.<sup>51</sup>

The reaction products of phenol or urea and formaldehyde can be fractionated to obtain resins of varying properties by treating the hot resin with the minimum quantity of water necessary for separation into 2 layers when cooled to 15°C. The aqueous layer can be further separated by repeating the procedure.<sup>52</sup>

Dent<sup>53</sup> used crude phenols in making resins for hot molding. He states that previous attempts with such raw materials failed because of difficulties arising on attempted dehydration. This he avoided by neutralizing the basic catalyst with an acid that leaves an insoluble residue in the mass. After this he added formaldehyde and ammonia to form hexamethylenetetramine to act as the catalyst for the final setting. He further stated that as this catalyst has little or no action below 100°C., the resin so made can be dried by heat and vacuum without risk of setting.

**Dry Processes.** One-stage and two-stage dry processes can be differentiated in the same way as the wet processes. Their use is practically limited, as mentioned before, to the production of material to be machine-turned or cast. The products are light-colored, and transparent, translucent or opalescent for such uses as substitutes for amber or tortoise shell. Dry operations are not usually applied at present to the preparation of fusible soluble resins. If a dry process is used it is generally carried out in one stage, directly to infusible insoluble resins, although it can be taken only to the stage of soluble fusible resins. If fusible soluble resins prepared by a wet process are hardened by addition of anhydrous aldehyde, although this second stage is really a dry operation, the entire method is considered a two-stage wet process.

The aldehyde commercially useful in dry processes is limited practically to paraformaldehyde as such or as hexamethylenetetramine.<sup>54</sup> Other anhydrous aldehydes, such as gaseous formaldehyde, various formaldehyde polymers, (trioxy-

<sup>54</sup> Strictly speaking the reaction between phenol and paraformaldehyde is not a dry process since it liberates water, but this classification into wet and dry grew out of controversies and has been continued in the industry.

methylene or metaformaldehyde, for instance) and acetaldehyde polymers (paraaldehyde and metaldehyde) have found no extensive application.

*Processes Using Hexamethylenetetramine.* In the dry state, hexamethylenetetramine<sup>55</sup> represents a rather costly material for the preparation of initial or fusible resins. More frequently, as may be expected, it is employed in small proportion as a finishing or hardening agent. As Baekeland indicated,<sup>56</sup> a fusible resin transformable by heat to an infusible body requires an added proportion of formaldehyde in its making, approximately 7 mols of formaldehyde to 6 mols of phenol being necessary. This amount of course may be supplied all at once or in two or more stages. Making fusible resins with the aid of one catalyst and transforming to an infusible resin in the presence of another catalyst constitutes the basis of scores of processes differing but slightly in details. That hexamethylenetetramine should be repeatedly advocated in such duplex processes is not surprising in view of its well known properties.<sup>57</sup>

Redman, Weith and Brock<sup>58</sup> considered the reaction between hexamethylenetetramine and phenol in aqueous solution to be substantially different from that progressing when the reagents are heated in a dry state. The simplest product which forms when phenol reacts with hexamethylenetetramine is the crystalline compound, hexamethylenetetraminetriphenol.<sup>59</sup> However, when 1 mol of hexamethylenetetramine and 6 mols of phenol are boiled in aqueous solution, a light yellow transparent viscous liquid separates which on continued heating increases in viscosity. At room temperature it becomes a brittle amber-like solid.

Lebach<sup>60</sup> stated that hexamethylenetetraminetriphenol, when heated in the dry state, evolves ammonia and yields an insoluble and infusible substance. Lebach considered this product to be Bakelite but this was challenged by Redman, who looked upon Bakelite as a material in which 6 phenols are united with 7 methylene groups. As hexamethylenetetraminetriphenol has a composition of 6 phenols for every 12 methylene groups, over 40 per cent more methylene is present than is required, according to Redman, to produce Bakelite. When hexamethylenetetraminetriphenol is heated, besides ammonia there is evolved a substance having an odor somewhat resembling methylamine. The latter by-product is not present when the phenol is increased to 6 mols of phenol for 7 methylenes. If, however, dry hexamethylenetetramine and anhydrous phenol are mixed and the mixture heated to 60°C or higher, a reaction begins with the evolution of ammonia which, according to Redman's investigation, is the only by-product. With phenol in excess and if the mixture is heated to the boiling point, the reaction proceeds with great rapidity. Nearly all the ammonia is evolved in the first 10 minutes of boiling. Representing the formula of hexamethylenetetramine<sup>61</sup> as  $N\equiv(CH_2-N=CH_2)_3$ , this reaction may take place

and a second reaction may occur:

<sup>55</sup> This substance, also called *formin*, but more commonly by the abbreviation "*hexa*," always forms when ammonia and formaldehyde are mixed. Therefore, when ammonia is added for catalytic purposes to a mixture of phenol and formaldehyde, hexamethylenetetramine is produced. See Chapter 16.

This continues until all the  $\text{CH}_2$  groups have combined with the phenol and ammonia remains as the by-product. The intermediate product aminosaligeno-saligenin has been isolated.

Heating a mixture of hexamethylenetetramine and an excess of phenol produces soluble and fusible resins (Novolak).<sup>42</sup> These are soluble in alcohol, acetone, and aqueous caustic alkali. The resin remains a liquid at temperatures up to  $180^\circ\text{C}$ . and even after being subjected to this temperature for many hours. When cold it hardens to a glassy material which is more brittle than common rosin. If the phenol is decreased below the ratio of 12 mols to 1 mol of hexamethylenetetramine, the liquid thickens and the resin changes to an infusible and insoluble transparent substance of yellow or red color. Nine mols of phenol to 1 mol of hexamethylenetetramine yield a complex which is quite brittle in the cold but rubbery when heated to  $170^\circ\text{C}$ . Eight mols of phenol to 1 of hexamethylenetetramine is brittle in the cold and when hot resembles gelatinized tung oil. As the phenol is reduced the reaction product becomes less elastic when hot and in the ratio of about 5 mols of phenol to 1 of hexamethylenetetramine is quite hard at all temperatures. At room temperature this is a dense tough product, the tensile strength of which ranges from 4000 to 5200 pounds per square inch. Decreasing the phenol below 5 or 5.5 mols to 1 of hexamethylenetetramine makes the resin brittle on account of the presence of an excess of crystalline hexamethylenetetraminetriphenol.

A mixture of phenol (6 mols) and hexamethylenetetramine (1 mol) on heating strongly, for example at  $180^\circ\text{C}$ ., evolves ammonia rapidly and produces a spongy material. This may be ground readily and when pressed in hot molds at 4 to 6 tons per square inch yields a homogeneous transparent solid article, of good mechanical strength and high dielectric properties, which is quite inert to reagents. If the same composition is heated on a water bath for 25 hours, less than half of the total ammonia is evolved and the mass is viscous when hot and brittle when cold. Redman succeeded in casting in open molds mixtures made in these proportions, allowing hardening to take place by heating without application of external pressure. Transparent rods 2 feet long and  $1\frac{1}{2}$  inches in diameter free from fractures and gas bubbles were obtained.

Aylsworth<sup>43</sup> utilized organic acid anhydrides, such as benzoic or phthalic anhydride, to absorb or fix the ammonia liberated during the final reaction when hexamethylenetetramine is used. In addition to absorbing ammonia by forming amides, these anhydrides were stated to be valuable in toughening the resin. Anhydrides of some acids also combine with water and thus remove any water liberated during the reaction. Higher members of the acetic acid series, for example, stearic anhydride, have also been used by Aylsworth.

Baekeland<sup>44</sup> prepared amber-like products by heating phenol and hexamethylenetetramine, with or without water, to form hard, infusible resins containing free ammonia.

The reaction between phenol and hexamethylenetetramine was carried out under anhydrous conditions by Goldsmith<sup>45</sup>. The proportions of the ingredients are such that one phenolic group is introduced to each methylene group. The mixture is heated, with the evolution of ammonia, until a sample solidifies on cooling. The product is soluble in ordinary solvents but can be hardened and made infusible and insoluble by further heating under pressure. The employment of a solvent facilitates control of the reaction and produces a more homo-

geneous resin. Goldsmith<sup>66</sup> used xylene as a solvent to moderate the reaction. If the amount of xylene is large, the resin separates during the latter part of the process either as a solid mass or as a pulverulent precipitate. For example, 40 g. of phenol, 10 g. of hexamethylenetetramine and 50 g. of xylene are heated together under a reflux condenser, the temperature being slowly raised to about 165°C. when the product precipitates as a resinous mass and the xylene can be poured off and used again. Redman<sup>67</sup> heated 1 mol of hexamethylenetetramine with more than 5 mols of phenol in the presence of a solvent such as alcohol or acetone, which acts as a controlling agent and retards the reaction. After about 5 hours at 80° an initial condensation product can be used as a coating or binder, glue or adhesive. By subjecting it to further heat and pressure the material is transformed into a hard, infusible, insoluble resin. Glycerol can be added to the raw materials to make the final product more pliable and to produce a ruby-red color.

The substitution of hexamethylenetetramine, according to Redman, Weith and Brock,<sup>68</sup> overcomes a number of the difficulties which arise when aqueous formaldehyde is used. A molding composition may be prepared from 75 parts of hexamethylenetetramine dissolved in 300 parts of cresol and mixed with 600 parts of asbestos pulp and 150 parts of asbestos fiber. Pitch, asphalt or varnish resins may be added. The composition is molded by hot pressing to yield infusible articles. Hydrobenzamide or benzaldehydeamine may also be used with phenol, cresol or xlenols.

From phenol or cresol and hexamethylenetetramine Redman<sup>69</sup> made soluble fusible resins which could be treated with formaldehyde or more hexamethylene-tetramine to form hard, infusible, insoluble bodies. The mixture is in the proportion of 11 mols of phenol or 10 mols of cresol to 1 mol of hexamethylenetetramine. Thus, 103 pounds of phenol and 14 pounds of hexamethylenetetramine are heated to a temperature of 130°C., at which point reaction takes place with the evolution of heat. The temperature rises to 180°C. and ammonia is evolved. When ammonia ceases to come off heat is applied and the reaction product is boiled at a temperature of approximately 183°C. for a period long enough to eliminate most of the nitrogen (usually 5 hours). According to Redman, the resinous material consists of about 38 per cent of phenol and 62 per cent of phenyl-endekasaligeno-saligenin,  $C_6H_5(OCH_2C_6H_4)_{11}OCH_2C_6H_4OH$ . To prepare an infusible resin the batch is allowed to cool to about 105°C. and 15 pounds of actual formaldehyde (in the form of 40 per cent solution) and about one-half pound of hexamethylenetetramine are added. The mass is further cooled to a temperature of 65-75°C. and is held at this temperature until hardening takes place. When cresol is used, 1080 pounds of it and 140 pounds of hexamethylenetetramine are heated to 140°C. and the temperature is allowed to rise spontaneously while ammonia is being evolved. When the evolution of ammonia ceases, heat is applied and the batch is maintained at a temperature of 165°C. for 48 hours. A portion of the free cresol (as much as 10 to 30 per cent of that originally used) is eliminated by blowing hot air through the fused mass. Then 78 pounds of creosote oil are added at a temperature between 85° and 125°C., and 120 pounds of hexamethylenetetramine are introduced, together with small amounts of dyes, pigments, fats or waxes. This material is mixed with fillers by treating on milling rolls to form a sheeted product which is ground to a powder for molding.

**Use of Polymers of Formaldehyde.** Aylsworth<sup>70</sup> heated a formaldehyde compound (having the formula  $[\text{CH}_2\text{O}]_n$ , in which  $n$  is less than 4) at a temperature not exceeding  $180^\circ\text{C}$ . with an anhydrous fusible phenol resin for a length of time sufficient to cause complete hardening. The proportions of the two reacting bodies are determined by ascertaining the amount of free phenol in the phenol resin and calculating the amount of formaldehyde compound necessary for complete combination to form a hard infusible resin.

*Courtesy Bakelite Corp.*

FIG. 61.—Micarta Serving Tray with Inlaid Metal Design.

The production of light-colored phenol-formaldehyde resins depends, according to Pollak, on the use of a minimum amount of condensing agent and the removal of excess phenol by washing with warm water. The use of a sensitive form of trioxymethylene ( $\beta$ - and  $\gamma$ -polyoxymethylene) makes the addition of a special catalyst unnecessary. A method employed by Pollak<sup>71</sup> consists in adding anhydrous trioxymethylene (20 parts) to phenol (370 parts) and metacresol (6 parts) heated on a water bath. Reaction begins at  $85^\circ\text{C}$ . with the evolution of heat and the temperature rises to above  $100^\circ\text{C}$ . After the temperature has fallen below  $100^\circ$  additional trioxymethylene is added and the heating and cooling allowed to take place after each addition until 80 parts of the methylene compound have been introduced. The mass is repeatedly washed with large quantities of water at a temperature below  $40^\circ\text{C}$ . and is then heated to about  $130^\circ\text{C}$ . The resin is used as a substitute

<sup>70</sup> J. W. Aylsworth, U. S. P. 1,102,630, July 7, 1914; *J.S.C.I.*, 1914, 33, 931.

for shellac. Discoloration of the resin on exposure to light and air is considered by Pollak<sup>72</sup> to be caused by the presence of small amounts of leuco bases, which gradually oxidize to colored substances. These may be washed out of the resin along with free phenol. A soft resin, therefore, is prepared and very thoroughly washed first with water and then with water containing methyl alcohol or acetone.

In one instance, Pollak heated 100 parts by weight of crystallized phenol with 80 parts of 40 per cent aqueous formaldehyde in the presence of 0.2 part of sodium phenolate. The heating is carried out under reflux until the condensation product precipitates. The heavier resinous layer is separated from the supernatant aqueous solution and is washed repeatedly with water, followed by water containing 10 per cent of methyl alcohol and finally by cold water. The residue is freed from the last traces of phenol by distillation *in vacuo*. When heated in molds at 95-120°C., the infusible and insoluble product is transparent, of a light yellow color and is stated to be air- and light-proof. In another case Pollak treated 94 parts of crystallized phenol with 15 parts of finely powdered  $\alpha$ -polyoxymethylene and added enough 1/5 *N* sulphuric acid to start an exothermic reaction and to dissolve the polyoxymethylene. The mixture is heated to about 85°C., 5 additional parts of polyoxymethylene and a further quantity of the sulphuric acid solution being added after the reaction has started. The soft resinous mass is washed repeatedly with water and treated with a 0.3 per cent solution of hydrogen peroxide. After standing for some hours the resin is further washed with water. This material is an intermediate which when mixed with fresh formaldehyde or polyoxymethylene can be converted into a light- and air-proof insoluble product.<sup>73</sup>

If phenol or cresol is heated with an excess of paraformaldehyde in the absence of a catalyst (1 mol of phenol to 1½ mols of paraform) an oily liquid is formed, which becomes solid at a high temperature.<sup>74</sup> When this liquid condensation product is mixed with a soluble fusible phenol-formaldehyde resin in the presence of acid or alkaline catalysts and heated, the final products are insoluble and infusible, although soluble intermediates may be obtained.<sup>75</sup> Snelling,<sup>76</sup> in a somewhat similar manner, prepared one intermediate substance from a phenol and hexamethylenetetramine and a second from a phenol and an anhydrous polymerized aldehyde. These two products were then mixed in such proportions that the excess of ammonia in the first compensated for the deficiency in the second.

A process proposed by Morgan and Drummond<sup>77</sup> consists of heating a mixture of a phenol, a solid polymer of formaldehyde, a catalyst such as lime or hydrochloric acid, and an inert organic solvent. The resin solution produced is neutralized and washed, preferably with saturated sodium thiosulphate solution, and dried.

Another form of anhydrous aldehyde, namely, gaseous formaldehyde, was used by Aylsworth.<sup>78</sup> Formaldehyde gas is introduced with agitation into an autoclave containing phenol or cresol held at a temperature of 125-170°C. Pressure is maintained slightly in excess of the vapor tension of the mixture by feeding the compressed gas into the autoclave as rapidly as it combines with the phenol. At 50-100 pounds per square inch very good results are obtained. The operation is continued until a sample shows 12 per cent or less of free phenol. The resulting resinous product is dehydrated at 205°C. and is cast into slabs for subsequent use. Aylsworth<sup>79</sup> produced molded articles by placing phenol in a heated mold and resinifying it by introducing gaseous formaldehyde under pressure.

## PHENOL-ALCOHOL RESINS

The phenol alcohols (see Chapter 14), such as saligenin or hydroxybenzyl alcohol, as well as dihydroxydiphenylmethanes, have been shown to serve as intermediates in the formation of phenol-formaldehyde condensation products. These materials, being crystalline, offer themselves readily to purification. Other crystalline intermediates, such as those obtained from condensation of acetone and phenol, which can also be used for the preparation of resins, are described in Chapter 18.

Methods of forming phenol alcohols from phenol and formaldehyde have been described by Manasse,<sup>80</sup> Lederer,<sup>81</sup> and Granger,<sup>82</sup> as already mentioned.<sup>83</sup>

Infusible molded articles were made by Baekeland<sup>84</sup> from hydroxybenzyl alcohol or other phenol alcohols. In one case phenol alcohols or their anhydrides (sahretins) and formaldehyde, with or without a condensing agent, are heated to give hard thermo-rigid resins. In place of formaldehyde, its polymers may be used. When ammonia is employed as a condensing agent hexamethylenetetramine is produced which of course serves as a hardening agent. In the infusible state the resin may be incorporated with a variety of filling materials (asbestos, wood fiber, mineral powders and pigments) in the same manner as is employed in making rubber compositions. Organic substances such as naphthalene, anthracene, aniline, phenols, pitch, asphaltum, cumarone resins and other resinous bodies and paraffin may be added. Another procedure is that of treating phenol alcohols or their anhydrides with basic catalysts to yield resinous substances which are less hard and less resistant to heat and to solvents than the products obtained above with the aid of additional formaldehyde. Appropriate catalysts are ammonia or its carbonate, caustic alkalies or their carbonates, aniline, pyridine, barium or calcium hydroxides, alkali sulphides, acetates and cyanides, borax, soaps and trisodium phosphate. Fillers may be incorporated with the resinous material thus obtained and the composition molded under heat and pressure.

Aylsworth<sup>85</sup> prepared phenol alcohols by reacting phenol and formaldehyde in the presence of an alkaline solution such as milk of lime. The product is mixed with fillers, with or without the addition of hexamethylenetetramine, and is treated with an acid to neutralize the alkali. The resultant composition is dried and is then available for molding. The process also is adapted for preparing varnishes and lacquers.

Amann and Fonrobert<sup>86</sup> prepared definite phenol alcohols, free from resinous and other by-products, by slowly adding a mono- or dicyclic phenol (phenol, cresol, naphthol or dihydroxydiphenylpropane), particularly in alkaline solution, to a quantity of aldehyde at least equal to the theoretical amount that can combine with the phenol. The oily product can be converted into infusible bodies under heat and pressure by treating them with further quantities of formaldehyde.<sup>87</sup> Baekeland<sup>88</sup> obtained a soluble composition (which could be rendered insoluble

by further heating) from hexamethylenetetraminetriphenol and a phenol alcohol, for instance, hydroxybenzyl alcohol.

Sutherland<sup>90</sup> heated hydroxybenzyl alcohols, hydroxy  $\beta$ -naphthol alcohols or trihydroxybenzyl alcohols, at about 100°C. with the cyclic ether of a polyhydric alcohol in the presence of an acid or alkaline condensing agent to produce infusible products. Cyclic ethers of polyhydric alcohols proposed are formalglycerol, formalglycol, acetalglycerol and benzalglycol. Catalysts suggested include formic, hydrochloric and phosphoric acids and sodium hydroxide, calcium hydroxide and sodium carbonate. Thus, 50 parts of o-hydroxybenzyl alcohol, 50 parts of formalglycerol,

and 3.5 parts of 30 per cent ammonium hydroxide are heated at 70°C. for 2 to 3 hours and then poured into an open vessel, the temperature being gradually raised to 100°C. When the product becomes solid, the temperature is increased rapidly to about 125°C. and maintained until the mass is fully cured. The product is a light yellow transparent, semi-rigid, amber-like solid, very flexible when heated, infusible, insoluble in all ordinary solvents, highly resistant to acids and many alkalis, and possesses high dielectric properties.

Kulas and Pauling<sup>91</sup> prepared phenol-aldehyde resinous condensation products by condensing methylenephenols and phenol alcohols. A methylene-diphenol mixture is prepared by the action of an acid such as hydrochloric acid on a phenol and formaldehyde; phenol alcohols are formed by the action of a basic condensing agent upon an additional mixture of phenol and formaldehyde. As an instance, 50 parts of cresol are heated with 25 parts of 40 per cent formaldehyde and 1 to 1.5 parts of moderately concentrated hydrochloric acid to the point where separation begins, then 100 parts of cresol, 75 parts of 40 per cent formaldehyde and 20 to 25 parts of aqueous ammonia (25 per cent) are added. The mixture is boiled for a considerable time and then dehydrated to obtain a soluble transparent resin. By gradually heating the soluble body thus prepared it can be transformed into an insoluble form.

If the reaction between formaldehyde and an alkali phenolate is carried out at low temperatures, the amount of formaldehyde undergoing the Cannizzaro reaction (see Chapter 14), as compared with the amount entering into the condensation, is substantially lessened. Accordingly, it is desirable to keep the reaction mixture cold until all of the formaldehyde becomes bound.<sup>92</sup>

Polyalcohols of phenols, formed by using an increased proportion of formaldehyde in alkaline condensation with phenols, are converted into pale acetone-soluble resins by the addition of strong acids. These resins are said to have superior curing properties and to withstand the effects of light both before and after the cure.<sup>93</sup>

## CONTINUOUS PROCESSES

The advantages of continuous processes are at once apparent. In large digestors very careful control of the reaction is necessary, and an accident to the water-cooling system, for instance, might mean the loss of the entire large batch due to the uncontrolled heat of combination converting the mass to the infusible state. In a continuous system where reaction is confined to small quantities of material such loss would be relatively small. The more careful control of a continuous operation and its higher production rate are special advantages. The exothermic reaction of condensation can also be made to preheat the fresh reaction mixture.

Turkington<sup>93</sup> proposed to mix the phenol, formaldehyde solution and catalyst and to pump the mixture continuously through heated reaction coils. A steam piston pump capable of producing a pressure of a few hundred pounds per square inch is used and the pressure is maintained by an adjustable pressure regulator.

Fig. 62.—Continuous Process for the Production of Phenol-Formaldehyde Resins. (V. Turkington.)

From the pump the mixture passes through a reaction coil, formed of extra heavy iron or copper tubing immersed in an oil bath. The bath is heated by a closed steam coil supplied with steam at about 125 pounds pressure to initiate the reaction. The coil may also be supplied with water connections for cooling, should this be required. The reaction is exothermic and the heat of reaction ordinarily suffices to maintain the proper temperature of the oil bath.

The reaction mixture is forced slowly through the heating coil, where the flow and bath temperature are regulated to complete the reaction to the desired point before the mixture passes the discharge end of the coil. The rate of flow will depend largely on the length of this coil. On passing from the coil the reaction mixture is a fluid material containing a large proportion of water. This mixture is dehydrated by spraying into a chamber in which a relatively high vacuum is maintained. The resin is then cooled to 50°C. or lower which prevents further reaction. See Figure 62.

Another continuous process consists in introducing the reactants into a preheater (a heated copper coil) and atomizing the mixture or distributing the reaction product upon rollers or endless belts during the heating with or without a previous passage through a water separator. The finished resin may be used as it leaves the concentration plant, for example by passing it directly to a paper-sizing machine.<sup>94</sup>

Hoskins<sup>96</sup> suggested a process utilizing a silent electrical discharge in which phenol and formaldehyde are vaporized in two separate stills and passed into a tubular treating conduit surrounded by a hot-water jacket. The conduit itself is one electrode and surrounds the other of a high-voltage electric circuit. In this way the mixed reagents in the vapor state are subjected to a silent electric discharge. The vapors are condensed on emerging from the conduit, and the condensate is heated to evaporate phenol and formaldehyde. About 40 per cent of the original material remains as a clear, brown, brittle resin, soluble in alcohol and ether mixtures but only slightly soluble in alcohol alone. The process is best carried out at reduced pressure. The resin on heating at 280°C. or above for any appreciable length of time becomes insoluble.

#### PURIFICATION OF RESINS

The questions of the action of light and air on phenol-formaldehyde resins and resinoids and of purification processes to minimize this have received much consideration. It is well known that exposure to light often has a darkening effect whether these resins are in the form of coatings, moldings or fabricated resinoids.

One explanation for the darkening is that it is caused by free phenol. Pollak<sup>98</sup> on the other hand laid it to the presence of small amounts of leuco bases which gradually oxidize to colored substances.<sup>97</sup> Pollak<sup>98</sup> used acid catalysts and found the amount of acid to be the controlling factor of color in the finished resin. When the quantity of acid used is less than 1-2 per cent of the end product perfectly white or slightly brownish or yellowish products result. However, in considering the causes of the dark color assumed by novolaks, Mashkilleison and Zimmerman<sup>99</sup> concluded that neither the presence of free phenol (up to 4 per cent) in the finished product, nor the purity of the phenol, nor the amount of catalyst is of importance. In all cases studied by them there was a considerable change in the original color after 30 days' exposure to light. The nature of the catalyst to a large extent influences both the original color and its stability. From the standpoint of color permanence, best results are obtained with weak mineral acids. Strong mineral acids and organic acids give poorer results and the least satisfactory are the metallic salts of mineral acids.

Redman, Weith and Brock<sup>100</sup> found that even the brightest light does not affect a phenol resinoid that is kept out of contact with oxygen. They observed that non-oxidizing gases (carbon dioxide, methane and ordinary illuminating gas) or the absence of air (vacuum) tend to prevent darkening even if the sample is placed in direct sunlight. Such methods for preventing darkening are far from practical, and various others have been proposed, as previously mentioned, for removal of the substances which cause darkening. Pollak<sup>101</sup> suggested washing the resin with warm water; Hessen<sup>102</sup> treated the liquid resin with additional formalde-

hyde to combine completely all the phenol; Ostersetzer and Riesenfeld<sup>103</sup> made powdered hardened resins in emulsified dispersions and thus reduced impurities by decreasing their adsorption of substances from the mother liquor; Moss<sup>104</sup> used sodium phosphate ( $\text{Na}_2\text{HPO}_4$ ) as a condensing agent; Melamid<sup>105</sup> esterified the resins with p-toluenesulphonyl chloride; and Pfautsch<sup>106</sup> treated the phenol itself with sodium bisulphate and thiosulphate and distilled it before use to make light-stable resins. Blumer<sup>107</sup> stabilized the color by oxidizing the resin with persulphates or perborates. Manganese dioxide, lead oxide, lead chromate, sodium chromate, ammonium dichromate and potassium permanganate are said to be useful in maintaining the brilliancy of phenol-formaldehyde resins.<sup>108</sup>

Ehrlich<sup>109</sup> treated the intermediate substances obtained from phenols and formaldehyde with acids (lactic, acetic, tartaric, or boric) to obtain pale-colored resins stable to light and air. The resinous condensation product obtained by heating phenol with 40 per cent formaldehyde solution in the presence of sodium carbonate is washed with hot water until it becomes thick and viscous and then with 4 per cent acetic acid. The resulting thin resin is washed again with water and, after the addition of a small quantity of ammonia, is dehydrated *in vacuo* and hardened in the usual way. The resulting transparent, colorless or faintly yellow material is insoluble in acids and alkalies, and, because of the absence of excess phenol, is stable to light and air.

Distillation of the uncombined phenol from a resin, even under reduced pressure, is ineffective since the last traces are extremely difficult to remove and even small traces are enough to have considerable effect. However, the color-forming constituents are removable from the readily condensable intermediate products before the hardening by extraction with such solvents as ether.<sup>110</sup>

Drummond<sup>111</sup> treated resins made from phenol and formaldehyde with the vapor of an organic solvent (ethyl alcohol), of lower boiling point than water and preferably miscible with the resin, until no further free phenol is removed. The purified substance may be used directly in solution or it may be freed from solvent by heating *in vacuo*.

Purified resins are also obtained by washing successively with hot water, dilute mineral acid, and cold water. The products may be made insoluble by heating to 100°C. or they may be dissolved in appropriate solvents (alcohol, acetone, or amyl acetate) to form varnishes or lacquers. The purified products combine with bases such as lime or ferric oxide, and with glycerol.<sup>112</sup> Bucherer<sup>113</sup> heated phenol-aldehyde resins with a dilute alkaline solution to effect purification.

Various washing procedures were used by Seebach to remove free phenol in purifying resins. Crude fusible phenol-aldehyde compositions may be treated with

alkali<sup>114</sup> or alkaline-earth<sup>115</sup> hydroxides to combine with free phenols and the reaction by-products to form water-soluble salts but no excess is allowed to remain to combine with the resin. Suggested oxides and hydroxides are those of calcium, barium, strontium, magnesium, aluminum, copper, zinc, nickel, or such combinations with alkalies as sodium aluminate, potassium zincate, or sodium zincate. Organic solvents<sup>116</sup> for the resin can be used during or after the action of the metallic oxides, the solvents being completely or incompletely miscible with water as desired. The resins are precipitated by the addition of water, acid or such salts as sodium chloride, magnesium sulphate, alum; or the process may be modified by the addition of salts, such as sodium saheylate or alkali metal soaps which have the property (hydrotropism) of rendering soluble, substances which are insoluble in pure water. The metallic oxides which have not combined with the phenols, Seebach stated, may be allowed to remain in the subsequently precipitated resinous condensation products as filling materials. The process is described approximately as follows:

One hundred kg. of coarsely ground resinous phenol-aldehyde condensation product are mixed for 2 to 3 hours in a ball mill with 200 l. of lime water (containing 6 kg. of quicklime) to form a colloidal solution. The precipitated material is a fine powder which is separated by filtration, centrifuging, or decantation from the liquid and washed with water. The resin may be dried at 30-40°C. This process usually raises the melting point of the resin.

Another proposal by Seebach<sup>117</sup> is the use of fluxing agents in the distillation of permanently fusible resins to free them of uncombined phenols. For this purpose he recommended high-boiling organic substances such as glycerol, ethylene glycol, phthalic, or lactic esters,  $\alpha$ - or  $\beta$ -chloronaphthalene, dichloronaphthalene, tetrahydronaphthalene, decahydronaphthalene, or cyclohexanol and its esters. Fluxes may also include urea or thiourea. For example, 2120 parts of fusible phenol-formaldehyde resin (novolak) and 280 parts of glycerol are distilled *in vacuo*. The distillate amounts to about 306 parts and the residue when cold is almost colorless and free from phenol.

The observation was made by Baekeland<sup>118</sup> that the initial resinous condensation product of phenol when undiluted may be hardened to the infusible condition at temperatures as low as 70°C. When, however, alcohol is added the resulting solution may be boiled under a reflux condenser for a long time without noticeable hardening. Baekeland found that water does not retard the reaction. On heating a solution of phenol-formaldehyde resin in aqueous sodium hydroxide to 80°C. the solution gelatinizes and on further heating hardens rapidly, yielding a transparent infusible product. The solution may be used as a heat-hardening varnish, or may be mixed with appropriate fillers for molding. Seebach<sup>119</sup> observed that a solution of phenol-formaldehyde resin in aniline hydrochloride could be heated for long periods without polymerizing and proposed the following distillation procedure for removing free phenol: 500 kg. of fusible phenol-aldehyde resin are dissolved in a well-stirred solution of 250 kg. of aniline hydrochloride (or salts

of other aromatic or aliphatic amines) in 250 kg. of water at 50-60°C. Distillation is then carried out at atmospheric or reduced pressure until 1000-2000 kg. of water have been distilled off, this water being replaced from time to time by additions of hot water to keep the volume unchanged. On adding water to the residue after the phenol has been removed by this distillation, the purified resin is precipitated and the aniline hydrochloride or other salt remains in solution. Organic solvents may be used instead of water and the resins may be washed with hydrotropic salts, if preferred.

For purifying soluble fusible phenol-aldehyde resins, Strafford and Walker<sup>120</sup> incorporated them with an inert filler such as wood flour, cotton waste, asbestos, or china clay and extracted this mixture with water or an organic non-solvent such as benzene. When water is used as the solvent they adjusted it to a  $pH$  of 6 before extraction. After filtering, the extracted material thus treated may be used as a molding powder or the resin may be dissolved out with acetone or alcohol and used in varnishes. The process is also applicable to the purification of sheets impregnated with resin used in making laminated board.

Waterman and Veldman<sup>121</sup> modified this procedure by using a suspension of sawdust in water, into which the liquid condensate was stirred. After agitating

for several hours, the resin-sawdust composition was separated by centrifuging, washed and dried. Only a faint odor of phenol or cresol could be detected. Cresol was also satisfactorily removed by employment of a suspension of kieselguhr or fuller's earth in benzene.<sup>129</sup>

The molding powder thus secured is reported to be completely freed of phenolic bodies by treatment with an acid diazonium solution.<sup>129</sup> Two g. of aniline (as hydrochloride) was diazotized with sodium nitrite solution and diluted to 2 liters. This was stirred while cold with 100 g. of the powder, followed by filtration and washing. The odorless product dried to a light brown color.

A bleaching process proposed by Stuhlmann<sup>124</sup> consists in subjecting the resins in cold alkaline solution with continuous stirring to the simultaneous action of formaldehyde and a bleaching agent such as hydrogen peroxide or sodium perborate.

To avoid discoloration of resins in course of manufacture, Kline<sup>125</sup> used acid-resistant materials (glass, porcelain, enamel or chromium) at all points of contact in the reaction apparatus.

#### DEHYDRATION

When a wet process is employed, the final dehydration is usually carried out in the same digester in which the resin is prepared, with or without the help of a vacuum. After the water has been removed, the resin is allowed to flow through a bottom discharge into pans for cooling.<sup>126</sup> If the resin is to be used for varnishes, the dehydrated resin may be left in the digester, solvents added, heat applied, if necessary, and the entire manufacture of the varnish completed in the same kettle. These methods work well with soluble fusible resins of the two-stage type.

The dehydration of the one-stage resin is somewhat more difficult by this procedure, since there is danger of gelatinizing the resin. Various methods have been proposed to overcome this. One consists in agitating the material (containing, e.g., 7 per cent of water) with an amount of propyl alcohol equal to its water content and pouring off the liquid which settles out from the mixture. The water, water-soluble materials, and colored impurities that may be present are removed simultaneously.<sup>127</sup> Another method was proposed by Kulas<sup>128</sup> in which the resin, cooled after separation from the reaction mixture, is centrifuged.

Hessen<sup>129</sup> heated the solid soluble fusible products in thin layers at 100-200°C. for one or more periods of 15-30 seconds with rapid cooling after each heat treatment. In this manner most of the volatile constituents are removed and the resins are partly converted to the insoluble infusible state. This semi-hardened product is subsequently worked up with further hardening agent. Clear transparent moldings are obtained by hot-pressing.<sup>130</sup> Volatile substances can also be

removed by powdering the resin and heating it under vacuum at a temperature below its fusing point.<sup>131</sup>

Spray-drying is said to be advantageous in dehydrating heat-sensitive resins. The aqueous mixture can be sprayed into a stream of air or other gas at 250-300°C. and the dried particles are then rapidly cooled by directing them into a low-temperature zone or upon a cold metal surface.<sup>132</sup>

Novotny<sup>133</sup> also proposed an atomizing or spray-drying process. The material is atomized and quickly wetted by directing the spray into water. The sudden chilling prevents fusion and the water removes impurities. As the solid resin absorbs no moisture the particles are readily separated from the wash water. The surface moisture on the resinous particles is quickly removed and the product easily dried. For drying a relatively wet, sludge-like synthetic-resin mass containing occluded water or mother liquor, Novotny cooled it, by mechanical refrigeration preferably, to a temperature at which it becomes solid and can be mechanically ground, but below that at which the ground particles agglomerate. The finely ground particles are then dehydrated by air currents. This type of drying is said to be particularly useful for resins made by the one-stage wet process. Petrov<sup>134</sup> suggested dehydrating by heating resins to 100-180°C. in a medium of drying or semi-drying oils under ordinary or reduced pressure.

#### SOLUBLE RESINS FROM INSOLUBLE

A method for converting an infusible product into a fusible one after the reverse change has once occurred was developed by Aylsworth.<sup>135</sup> An infusible porous mass, made by heating phenol, formaldehyde (40 per cent aqueous solution) and a small amount of either an acid or a basic catalyst, is ground and baked at 175°C. to remove entrapped water and acid vapors. This product is heated for several hours at 230-290°C. in a closed vessel with approximately one-half its weight of phenol or cresol. By this treatment the resin is dissolved and converted into a fusible form. A mixture of phenol and naphthalene may be substituted for phenol or cresol as the solvent. If naphthalene is used, it is later removed by distillation. This method can be used advantageously to reclaim discarded or imperfect articles or scrap containing an infusible resin binder.<sup>136</sup>

Kulas and Pauling<sup>137</sup> accomplished a similar conversion by heating finely powdered infusible resins, free from lumps, with phenols at atmospheric pressure until they are either dissolved or converted into a uniform swollen paste and resinifying the free phenol by the addition of formaldehyde and an acid or basic catalyst. Heating a phenol-formaldehyde resin with dihydroxybiphenyl in the presence of manganese dioxide, yields a composition which is characterized by its solubility in fatty oils.<sup>138</sup>

Becherer<sup>139</sup> proposed heating an insoluble phenol-urea-formaldehyde compound with a phenol until dissolved (and partially reacted). Sulphonation of the resultant liquid yielded material applicable as a mordant or tanning agent.

A procedure which is applicable to masses containing cellulose filler is to heat them in an autoclave with a phenol and a substance which hydrolyzes the

cellulose (10 per cent hydrochloric acid). The product is rinsed with water and can be converted into a moldable resin by addition of hexamethylenetetramine.<sup>140</sup>

Infusible resins are also completely converted into fusible resins by heating them with aqueous alkalies to a temperature above the boiling point of the solution.<sup>141</sup> For example, 100 kg. of coarsely powdered infusible resin may be heated with 1000 l. of 5 per cent sodium hydroxide solution at 200°C. for 1 hour to accomplish this conversion.<sup>142</sup>

Sections of infusible and substantially insoluble condensation products may be united by moistening the faces to be joined with a liquid such as acetone or alcohol, coating the surfaces with fusible phenol-formaldehyde resin and heating the faces pressed together until the intervening film becomes infusible.<sup>143</sup>

# Chapter 16

## Phenol-Aldehyde Resins

### IV. Catalysts

The production of resins from phenol and formaldehyde is customarily accomplished with the aid of catalytic bodies. One of the important factors in determining the course of the condensation reaction is the nature of the catalyst employed. It has been noted by Baekeland<sup>1</sup> (see also Chapter 14) that acid catalysts favor the following series of reactions: phenol + formaldehyde  $\longrightarrow$  hydroxyphenylphenoxymethane (rearranges to dihydroxydiphenylmethane)  $\longrightarrow$  soluble, fusible product (Novolak)  $\xrightarrow{\text{HCHO}(\pm\text{NH}_4)} \text{Resinoid A} \xrightarrow{\text{heat}} \text{Resinoid B} \xrightarrow{\text{heat}} \text{Resinoid C}$  (infusible, insoluble). In the presence of alkali, the condensation tends to take place in the following stages: phenol + formaldehyde  $\longrightarrow$  hydroxybenzyl alcohol  $\xrightarrow{\text{heat}} \text{Resinoid A}$  (can be melted a limited number of times)  $\xrightarrow{\text{heat}} \text{Resinoid B}$  (becomes jelly-like with solvents)  $\xrightarrow{\text{heat}} \text{Resinoid C}$ .

It is immediately apparent that certain steps in the condensation process are more or less selectively favored by particular types of catalysts. While no complete theory correlating all the facts of acid and basic catalysis in the field of the phenolic resins has yet been advanced, nevertheless there exists a considerable amount of scattered information on the subject. The catalytic effects of acid and basic molecules<sup>2</sup> come into play in a very large number of chemical reactions. It is believed by Brönsted that these catalytic effects, often ascribed to hydrogen ions, are in reality caused by -onium ions of the  $\text{OH}_2^+$  type. (See also Chapter 4.)

Hydrochloric acid reacts with formaldehyde (in the absence of phenol) in such a manner as to leave the methylene group intact. The compounds which have been isolated from this reaction are dichlorodimethyl ether<sup>3</sup> and an ether of the structure  $\text{ClCH}_2\text{OCH}_2\text{OCH}_2\text{OCH}_2\text{Cl}$  Blanc<sup>4</sup> assumes that the initial product is chloromethyl alcohol, which is too easily hydrolyzed to accumulate in water solution. The mechanism<sup>5</sup> would then be:

The formation of these compounds is quoted at this point in order to illustrate the fact that formaldehyde has been found to have a different type of reactivity in acids than it has in alkaline solution. It is not to be implied that chloromethyl alcohols or ethers are intermediates in the phenol-aldehyde condensation. In dilute

alkaline solution, as is well known, formaldehyde undergoes polymerization which involves the reallocation of methylene hydrogens upon carbonyl oxygens.<sup>6</sup> Thus, formaldehyde exhibits two contrasting modes of reaction, depending on whether it is in acid or basic solution. This observation is in harmony with the fact that the course of the phenol-formaldehyde reaction depends in part upon the acidity or alkalinity of the catalyst.

Ordinarily, the choice of catalyst is governed by more pragmatic considerations than would be indicated in a study of the reaction mechanism. The early controversies and patent litigations probably drew attention to a wider variety of catalysts than might otherwise have been investigated. Furthermore, important properties of the resins could be varied by varying the nature or quantity of the catalyst. Both strongly acid and strongly basic condensing agents when used in large proportions affect metals, cause deterioration of fillers and attract moisture. Their presence is particularly objectionable in resins which are to be used as dielectrics. In the pages to follow mention will be made of many of the mineral acids, organic acids, acid and basic salts which have been recommended. Also, various alkaline materials, ammonia and ammonium compounds, ammonium derivatives, various amines, particularly methylamines, aniline and benzylamine, have been employed, and their applications as catalysts will be described in this chapter.

#### EARLY WORK ON CATALYSTS FOR THE PHENOL-FORMALDEHYDE REACTION

The early investigators, who studied the phenol-aldehyde condensation as a possible (but often disappointing) means of synthesizing crystalline compounds, used acid catalysts.<sup>7</sup> Baeyer<sup>8</sup> called attention to the resin which was formed when phenol reacted with formaldehyde in the presence of hydrochloric acid. He further observed that resorcinol and formaldehyde, in the presence of hydrochloric acid, gave an insoluble body which burned without melting. In these experiments, the formaldehyde was used in the form of the monoacetate of dihydroxymethane. Ter Meer<sup>9</sup> found that, through the use of a mixture of glacial acetic and sulphuric acids, methylal could be condensed with anisol, and di-(methoxyphenyl)-methane could be isolated. Kleeberg<sup>10</sup> reported that alkali-insoluble resins were obtained by reacting formaldehyde with phenol, resorcinol or catechol in the presence of hydrochloric or sulphuric acids. Hosaeus,<sup>11</sup> working with the reaction between  $\beta$ -naphthol and formaldehyde, to form methylenedi- $\beta$ -naphthol, found that strong acids were not necessary as catalysts, and that glacial acetic acid served the purpose.  $\alpha$ -Naphthol condensed with formaldehyde in the presence of acetic acid to form a yellow alkali-soluble resin.<sup>12</sup>

Lederer<sup>13</sup> proposed the use of alkaline catalysts in the phenol-formaldehyde condensation, and by employing milk of lime or baryta water he was able to prepare crystalline hydroxybenzyl alcohols. Manasse prepared a series of phenol alcohols by condensing homologues of phenol with formaldehyde in the presence of caustic soda, caustic potash, potassium or sodium carbonates, quicklime, zinc and lead oxides, zinc dust, sodium acetate or potassium cyanide.<sup>14</sup> The phenol alcohols were converted into resins by the action of heat.

## BASIC CATALYSTS

After phenol-formaldehyde products began to be commercialized, it was pointed out<sup>15</sup> that the addition of an organic or inorganic base in proper proportion to a mixture of phenol and formaldehyde yields products which have technical advantages over those obtained by simple heating or by the use of acids or salts as condensing agents. A wide variety of alkaline materials (e.g., ammonia, caustic alkali, alkali sulphites) was used, the quantities recommended by Baekeland being 0.5-10 per cent, and in no case above 20 per cent of the total reaction mixture. The products were usually semi-solid and could be converted into insoluble, infusible resins by heating at 120-200°C. under pressure. The undesirable properties of phenol-formaldehyde resins made through the use of strong caustic as a catalyst can be avoided in various ways. For instance, it is possible<sup>16</sup> to use proportions of alkali exceeding 20 per cent of the total weight of the reaction mixture, provided the excess alkali is neutralized with acid after the resin has formed. When such large amounts of alkali are used, subsequent neutralization can be effected not only by strong acid but by the addition of salts of aluminum, zinc, copper, iron, lead, nickel or cobalt, since these metals yield insoluble hydroxides.<sup>17</sup> Similarly, Stockhausen and Grühl used ferric and aluminum chlorides to control the degree of plasticity of phenol-formaldehyde resins made in the presence of caustic soda.<sup>18</sup> Alternatively,<sup>19</sup> excess alkali can be neutralized with stearic acid, a practice which, according to Aylsworth, results in resins of good insulating properties. Van Voorhout condensed phenol and formaldehyde with 0.5 per cent caustic soda, and avoided excess brittleness by adding glycerol and turpentine,<sup>20</sup> or by cooling the products before the condensation had progressed too far. This cooling was conveniently accomplished by adding alcohol, and then distilling it off in a current of air.

It should be noted that when the products of alkaline condensation of phenol and formaldehyde are treated with acids, certain difficulties in operating conditions must be taken into account.<sup>21</sup> As the liquid reaction mixture begins to thicken, stirring becomes extremely difficult or impossible. Consequently hardening tends to occur unequally throughout the mass. If very small quantities of acid are used, the difficulty is not so great, but the hardening requires a long time. Large quantities of acid not only cause non-uniform products, but also blistering and sticking in the mold. Because of these considerations, the acidification was carried out by Schmidt in the following manner. After the initial resin had been formed in the presence of 2 per cent caustic soda, the reaction mixture was neutralized by adding hydrochloric acid. Water was removed by vacuum distillation, and the liquid resin was drawn off and poured into a kneading machine. A small excess of acid (2 per cent of phosphoric or oxalic acids) was introduced. After the kneading operation, the mass was hardened in a rod press (see Chapter 67) or cooled and ground to form a molding powder.

Kulas and Pauling<sup>22</sup> prepared fusible soluble resins as initial condensation products of phenol and formaldehyde in alkaline solution. These resins were heated in molds at 80-100°C. under pressure, and became hard, but were still fusible and soluble. Conversion to infusible insoluble products was accomplished by heating at 120-140°C. at ordinary pressure.

In strongly alkaline condensations, the formaldehyde may react to form phenol alcohols or it may undergo a Cannizzaro reaction, forming methyl alcohol and alkali formate. The extent to which the latter type of reaction takes place is reduced by operating at low temperatures.<sup>23</sup>

Ammonia and its derivatives are the catalysts<sup>24</sup> perhaps most commonly used in commercial production of phenol-aldehyde resins, for these agents cause no undesirable degree of acidity or alkalinity. As noted in Chapter 13, the use of ammonia in similar condensation reactions had its beginnings prior to 1900. The present discussion will be limited to those investigations which seem to be best dealt with under the heading of catalysts. A considerable percentage of the total number of patents in the field of the phenol-formaldehyde resins make some mention of the possible use of ammonia or hexamethylenetetramine in conjunction with the particular process described. These processes are discussed in their appropriate chapters. As a permanent constituent of phenolic resins, ammonia is less objectionable than fixed alkalis. This fact is particularly true if the resins are to be used for their electrical properties.<sup>25</sup> Aylsworth<sup>26</sup> proposed the addition of phthalic anhydride as a means of neutralizing free ammonia. Paqué<sup>27</sup> noted a particular advantage in using ammonia as the catalyst, for the resins he obtained were permanently clear. These products were prepared by subjecting the intermediate resin to a pressure of 100 atmospheres at 130°C. It has been recommended<sup>28</sup> that the quantity of ammonia employed in condensing phenol and formaldehyde be from 1-10 per cent of the weight of the total reaction mixture. If aniline is used in place of ammonia, the quantity required is from 1-5 per cent. Wiechmann<sup>29</sup> obtained a condensation product which was viscous and syrupy at ordinary temperatures, anhydrous, non-hygroscopic and insoluble in water, when 100 parts of crystallized carboic acid were heated with 10-35 parts of paraform in the presence of dry ammonia. Filhol<sup>30</sup> produced infusible condensation products from phenols and formaldehyde by using ammonia or ammonium carbonate as a catalyst at 75-80°C. When the viscosity of the mixture had increased considerably, an acid catalyst, particularly ethyl sulphuric acid, was added. The final product was obtained by heating at a slightly raised temperature. The ethyl sulphuric acid may be added in alcohol solution, and the product used as a varnish. Also, a number of basic compounds, both organic and inorganic, were proposed, namely, strontium, cupric and aluminum hydroxides, pyridine, various cyanides, urea, guanidine carbonate and piperidine dithiocarbamate.

A light-colored resin was made by Kunisch<sup>31</sup> by condensing phenol and formaldehyde in the presence of ammonia and hydrogen sulphide, with the addition of carbon disulphide.

Fifteen to 45 cc. of carbon disulphide were added to 0.5 kg. of melted crystallized phenol,  $\frac{1}{4}$ -% l. of water saturated with hydrogen sulphide was introduced, then 0.5 kg. of 40 per cent formaldehyde, and finally  $\frac{1}{8}$  kg. of pure 24 per cent ammonia solution. The mixture was heated for 1-2 hours at  $140^{\circ}\text{C}$ ., allowed to cool, and the upper aqueous layer separated. The lower layer was heated for 12 hours at  $100$ - $110^{\circ}\text{C}$ ., and when cool was broken up, heated in molds to a temperature of  $150$ - $200^{\circ}\text{C}$ ., and submitted to a pressure of 150-300 atmospheres. The hydrogen sulphide may be replaced by thiophenol or other substances which evolve hydrogen sulphide under the conditions of the reaction. It is said to be advantageous to add to the mixture a metallic oxide or sulphide, preferably zinc oxide, in the proportion of 5-20 g. per kg. of phenol, omitting ammonia and hydrogen sulphide.

Ammonia may be used in conjunction with caustic alkali. When a mixture of ammonia and potassium hydroxide is the condensing agent,<sup>32</sup> there is obtained a resin whose surface color changes gradually upon exposure to an oxidizing atmosphere.

Cherry<sup>33</sup> stated that by using a mixture of a fixed base, such as caustic soda and slaked lime, and aniline potentially reactive resins are obtained which when molded under heat and pressure yield products hardening rapidly at lower temperatures and possessing greater strength than when ammonia is used alone.

Hexamethylenetetramine is stated to be essentially equivalent to a mixture of ammonia and formaldehyde in the phenol-formaldehyde reaction.<sup>34</sup> Salts of this amine (hydrochloride, sulphate, tartrate, oxalate) have been recommended. It was suggested<sup>35</sup> that these salts be used in quantity not exceeding 2 per cent of the weight of the resin ingredients. Hexamethylenetetramine is often used as a hardening agent for resins which may have been produced through the use of other catalysts. Thus, soluble fusible resins are combined with not more than 5 per cent hexamethylenetetramine in order to harden them.<sup>36</sup>

In the preparation of colorless resins, hydrazine may be used in place of ammonia.<sup>37</sup> Alternatively, hydroxylamine may be employed.<sup>38</sup> Rossiter and Davis<sup>39</sup> condensed phenols, in the presence of 1-10 per cent of their weight of dicyanodiamide, with aldehydes. In one example they heated 40 parts of phenol and 2 parts of dicyanodiamide dissolved in 27 parts 40 per cent formaldehyde at  $70$ - $80^{\circ}\text{C}$ . with agitation for 4-5 hours. The mixture was evaporated, or the aqueous layer was separated and the resin dried. A transparent product was obtained which was soluble in alcohol and could be converted into a hard transparent insoluble resin by heating at  $100$ - $120^{\circ}\text{C}$ .

Aminophenols were used by Baekeland for the purpose of assisting the condensation of phenols with formaldehyde.<sup>40</sup> Thus, hexamethylenetetraminetriphenol not only acts as a catalyst but provides a portion of the reactants also. Phenol derivatives containing basic groups in addition to hydroxyl groups (amino-

phenols, methylaminophenols, hydroxyquinoline, hydroxydiphenylamine) have been proposed as catalysts.<sup>41</sup>

The alkyl and aryl amines have been investigated to a considerable extent. The condensation of naphthol with formaldehyde was carried out by Helm<sup>42</sup> with amines or ammonium salts, the proportions being as follows. Two hundred and ninety parts of naphthol were dissolved in 150 parts of a 40 per cent solution of formaldehyde and 95 parts of aniline were added. The resinous product was proposed for use as a shellac substitute. Xylidines, toluidines, benzidine and diphenylamine are said to retard the hardening of resinous mixtures made from phenol and hexamethylenetetramine.<sup>43</sup> These aromatic amines are added at an intermediate stage in the condensation. Bender<sup>44</sup> reacted phenol with anhydroformaldehyde-aniline,  $(C_6H_5NCH_2)_2$ , the weight of the latter being twice the weight of phenol used, and a fusible potentially-reactive resinous product was formed. The aniline was removed at 210°C. without causing the resin to become infusible. Holmes and Megson<sup>45</sup> studied the comparative rates of condensation of various phenols in the presence of catalysts. With trimethylamine, the following increasing order of reactivity was established: p-cresol, phenol, o-cresol, m-cresol, symmetrical xlenol (*cf.* Chapter 17). Contrary to expectation, o-cresol did not show especial sluggishness, although it yielded less highly condensed products. A similar ordination was obtained when triethylamine was used as the condensing agent. With pyridine as a catalyst, the relative reactivity of o-cresol was different from that noted in the above series, for it condensed less rapidly than phenol and at a rate essentially the same as p-cresol. In one series of experiments the various catalysts used were (in the order of their increasing effectiveness) pyridine, ammonia, triethanolamine, isopropylamine, tripropylamine, n-propylamine, methylamine, ethylamine, dipropylamine, piperidine, diethylamine, triethylamine, trimethylamine, methylamine, sodium hydroxide and sodium carbonate.

Regal<sup>46</sup> condensed phenol and formaldehyde in the presence of compounds formed by the action of formaldehyde on tertiary aromatic amines. Dimethylaniline, 2 parts, for example, was boiled with 400 parts by weight of 40 per cent formaldehyde solution. One hundred to 150 parts of hexamethylenetetramine and about the same quantity of paraformaldehyde were then added and boiling continued. The formaldehyde stock was caused to react with 1000 parts of phenol. Edison<sup>47</sup> hardened phenolic resins by adding p-phenylenediamine in the proportion of 0.5-1 per cent of the total resin ingredients. Pyridine was used as a catalyst by Morgan and Megson<sup>48</sup> in condensing fractions of low-temperature tar with formaldehyde. Products which are rendered infusible and insoluble by heat and pressure were obtained when phenols were condensed with aldehydes in the presence of butylamine, monoethanolamine, diethanolamine, cyclohexylamine, dicyclohexylamine, cyclohexylethanolamine or dicyclohexylethanolamine.<sup>49</sup>

The use of an indophenol or indamine was proposed by Regal.<sup>50</sup> The catalyst was formed *in situ* by the reaction between p-aminodimethylaniline and phenol, followed by treatment with an oxidizing agent. One part of p-aminodimethylaniline

was heated for 1 hour on the steam bath with 1000 parts by weight of phenol. A small amount (0.05 part) of potassium permanganate was then added, followed by 800 parts of 40 per cent formaldehyde solution. The mixture was heated further until resinification had taken place. The resin obtained was of a bluish or green color, which coloration could be destroyed by the addition of dilute mineral acids. Acetanilide was used as catalyst by Hechtman.<sup>51</sup> Furfuramide<sup>52</sup> and hydrobenzamide have also received attention. Greenwald<sup>53</sup> made use of triethanolamine by mixing 100 parts cresol, 100 parts formaldehyde and 7.5 parts triethanolamine, and carrying out the reaction at approximately 100°C. After 60 minutes the supernatant aqueous solution was withdrawn, and the viscous resin was dried *in vacuo*. Fillers were added, and the mixture was hardened in molds at 100-140°C. It has been recommended<sup>54</sup> that 4 per cent urea, and a salt (e.g., KBr) be added to resins made by condensing cresols with formaldehyde in the presence of triethanolamine (see Chapter 17). Comparative experiments are said<sup>55</sup> to indicate that resins made from low temperature tars using triethanolamine as a condensing agent have lower break-down voltages than the corresponding resins made with trimethylamine or methylamine.

Singer<sup>56</sup> catalyzed phenol-formaldehyde condensations by means of chloroaminoaldehydes. Colorless resins were obtained by Jäger<sup>57</sup> by the use of ammonia as the principal condensing agent with the subsequent addition of dithiocarbamates of strong bases such as piperidine pentamethylenedithiocarbamate, dimethylaminedimethyldithiocarbamate or diethylaminedimethyldithiocarbamate.

#### ACID CATALYSTS

When condensation of phenol and formaldehyde is carried out with a strongly alkaline catalyst, acid may be added at an intermediate stage in order to neutralize the excess alkali (*vide supra*). When this is done, the rate of reaction is diminished, but if additional quantities of acid are introduced, acid catalysis begins to be effective, and an increase in rate ensues. Near the neutral point, the course of the reaction is such as to yield products which are converted into infusible masses by heat. Increasing the amount of acid results in formation of saliretins (Novolaks). Still further increasing the proportion of acid directs the course of the reaction to the formation of infusible resins.<sup>58</sup>

Lebach<sup>59</sup> found it advisable to prepare first a liquid condensation product of phenol and formaldehyde, this being accomplished ordinarily in the presence of alkali. Addition of hydrochloric acid caused solidification to take place. Blocks for newspaper printing were made in this manner. The liquid resin was found to penetrate the remote parts of the most delicate molds, so that very true replicas could be made. Eilersten<sup>60</sup> fused phenols with trioxymethylene, and treated

the product with sodium carbonate solution. Final condensation was carried out after the addition of phosphoric acid, and a white translucent resin was formed. Similarly, Karsten<sup>61</sup> heated fusible soluble resins at 225-250°C. with boric acid or boric oxide. Bruhat<sup>62</sup> converted a liquid product prepared by the reaction of phenol, cresol or naphthols with anhydrous polymers of formaldehyde (paraformaldehyde, trioxymethylene) in the presence of traces of alkaline catalysts, into an insoluble infusible product by the addition of organic acids (lactic, acetic, formic, oxalic, tartaric, citric, gallic, tannic). Small amounts of mineral acids, hydrochloric, sulphuric, phosphoric and boric may also be present. The conversion takes place in the cold but more rapidly on heating. The initial liquid product with the acids added can be used as a varnish, or for gluing together laminae of wood, wood and fabric. Fillers, such as pumice, sand, glass, emery, asbestos, may be incorporated and the properties of the product may be varied by addition of gelatin, glue, naphthalene or rubber. Vessels resisting chemical reagents can be made from the final product. Thiele<sup>63</sup> performed the condensation of phenol and paraformaldehyde in two steps, as follows. In the first step a large excess of phenol was used, and the reaction was carried out at 80°C. A clear product was formed. To this was added more paraform, mixed with borax. The thick syrup which was obtained was converted into a solid resin by adding an excess of acid (hydrochloric, boric, tartaric, ammonium chloride), and heating at 100°C. for several hours.

Kulas and Pauling<sup>64</sup> proposed a two-stage process for preparing phenol-formaldehyde resin employing an acid catalyst (hydrochloric acid) in the first stage and an excess of base (caustic soda) in the second stage.

The amount of base considerably exceeds 10 per cent (by weight) of the quantity of phenolic body, and is more than sufficient to neutralize all of the acid catalyst. As an example, 50 parts of phenols, 25 parts of 40 per cent formaldehyde solution and 15 parts hydrochloric acid (sp gr 1.15) were boiled together for about 10-15 minutes. To the resulting mass 120 parts phenol, 90 parts 40 per cent formaldehyde, 10 parts ammonia and 2.5 parts sodium hydroxide were added. The mixture was heated under reflux for about 30 minutes. After removal of water a resin which could be thermally hardened was formed.

Instead of employing acid catalysts merely for polymerizing initial condensation products made by the use of alkaline catalysts, many investigators have chosen to carry out the entire condensation with acid catalysts. In the preparation of Novolak, it was found that maximum color stability was attained by the use of a small amount of phosphoric acid,<sup>65</sup> although hydrochloric<sup>66</sup> acid is the catalyst commonly used. Weak acids such as hydrogen sulphide, carbon dioxide or sulphur dioxide have been investigated as catalysts. An addition compound,  $H_2S \cdot 2CH_2O$ , is capable of reacting with phenol<sup>67</sup> to give a resin. Heinemann, Harvey and Robinson<sup>68</sup> heated phenols or cresols and formaldehyde or its polymers first without a condensing agent to yield liquid hydroxybenzyl alcohol, and this product was heated in an open vessel with sulphur dioxide solution. The product can be rendered insoluble by further heating or treatment with basic catalysts. Heinemann<sup>69</sup> obtained condensation products from phenols or cresols and formalde-

hyde by passing sulphur dioxide into the mixture of reactants, or the hydroxybenzyl alcohol made from them, and allowing the reaction to proceed without the application of external heat. The process was carried out in the absence of a solvent. According to Sarason,<sup>70</sup> condensation of phenols with formaldehyde proceeds more smoothly with sulphur dioxide as a catalyst than when strong acids are used. The products are alkali-soluble.

McCoy<sup>71</sup> effected the condensation in the presence of carbon dioxide. The reaction was interrupted when the product had become infusible and insoluble but was still capable of being softened by heat. After shaping, the material was further heated. Conducting the process in an atmosphere of carbon dioxide served to obviate the use of any other condensing agent. McCoy also proposed to obtain formaldehyde by the reduction of carbon dioxide with palladium hydride and permit the formaldehyde thus obtained to react in the presence of carbon dioxide as a condensing agent to produce resins. The palladium hydride could be regenerated by warming in a current of hydrogen gas. The process was carried out by passing carbon dioxide into a vessel containing the hydride suspended in water. Only a part of the carbon dioxide was reduced. The mixture of carbon dioxide and formaldehyde was passed into a second vessel containing phenol or cresol.<sup>72</sup> It has also been proposed<sup>73</sup> to condense phenol and formaldehyde by adding formic acid to the mixture, and heating under reflux for 1-2 hours. The viscous product was poured into molds and hardened first at 70-90°C., then, finally at 100-130°C.

Various strong acids besides hydrochloric have been found applicable in condensing phenols with formaldehyde. Birkby<sup>74</sup> used dilute sulphuric acid in the proportions of 500 volumes of phenol or its homologues, 450-550 volumes of 40 per cent formaldehyde, and 2-6 per cent by volume (relative to the volume of phenol) of dilute sulphuric acid. The latter was prepared by mixing 20 volumes of acid of 1.84 specific gravity with 80 volumes of water. The resinification was effected at a temperature of 60-80°C. After reaction and removal of water, the mixture was neutralized by milk of lime and the remaining water removed by heating *in vacuo*. The product could be finally hardened by heating under pressure. Melamid<sup>75</sup> also recommended dilute sulphuric acid as a phenol-aldehyde catalyst. Aylsworth<sup>76</sup> resinified phenol with a formaldehyde solution or with paraform, in proportions suitable to form an infusible product in the presence of sulphuric acid. When the reaction was partially complete a substance, such as barium carbonate, capable of forming an insoluble, electrically insulating salt with the mineral acid, was added, the quantity used being at least sufficient to combine with the whole of the acid present in the mass. Brunner<sup>77</sup> employed dry hydrogen chloride (see Chapter 17), and the resinous products were found to contain substituted chlorine.

It is possible to carry out the initial phase of the condensation of phenol with aldehydes in the presence of two catalysts, a mineral acid and a fatty acid. The mineral acid can then be removed, and the remainder of the condensation is catalyzed by the fatty acid alone.<sup>78</sup>

Alkyd resins<sup>79</sup> (see Chapters 41-49) have been proposed as catalysts for phenol-formaldehyde resins. A hardenable resin is made by reacting 1 mol of phenol, more than 1 mol of formaldehyde and 0.01-0.15 mol of an alkyd resin having an

acid number of 140-210. The alkyd resin is preferably in the C stage and the resinifying reaction carried out at temperatures not above 130°C.

#### SULPHONATED COMPOUNDS

Sulphonated phenol-formaldehyde resins are discussed in Chapter 20. The present section is concerned with the use of various sulphonated derivatives as catalysts. During the early years of the World War a group of resins termed "Carbolites" was developed in Russia. Essentially, many of these were phenol-formaldehyde resins prepared in the presence of various quantities of sulphonated mineral oil. The amount of the latter in the final product was usually from 0-15 per cent (based on the formula  $C_{20}H_{27}SO_3H$ ) of the total. A typical procedure<sup>80</sup> was as follows:

One hundred parts of phenol, 30 parts sulphonated naphtha and 38 parts of 34 per cent formaldehyde solution were heated together, and the initial condensation product was separated from the water formed. Additional formaldehyde was then introduced in quantity sufficient to bring the total formaldehyde content (calculated as absolute  $CH_2O$ ) up to about 1/3 of the total phenol content. The material was placed in molds and hardened at 95-100°C. The sulphonated naphtha used as catalyst was not a pure sulphonic acid, but contained, in some cases, only about 45 per cent sulphonic acid based on the formula  $C_{20}H_{27}SO_3H$ . The Carbolites are infusible and insoluble, and, accordingly, are different from the "syntans" described in Chapter 20.

The catalyst<sup>81</sup> used in the preparation of the Carbolites is prepared by treating dry petroleum distillate ( $d=0.883-0.898$ ,  $N_{16}=1.49-1.50$ , Engler viscosity at 50°C., 1.47-1.95) with 5 per cent oleum (27 per cent  $SO_3$ ), and permitting the mixture to stand for a day. Then the acid layer is run off, and the remaining oil is aerated.

Various modifying agents have been used in conjunction with the Carbolites. Thus, Petrov<sup>82</sup> mixed phenol with glycerol prior to condensation with formaldehyde in the presence of sulphonated fatty acids or naphtha sulphonic acids. (See also Chapter 20.) The initial product was washed with water, neutralized with alkali and heated with additional formaldehyde. After cooling, the resin was mixed with hydrochloric acid and cast into molds to be thermally hardened. The molded articles were said to possess good dielectric properties. The mechanical and chemical properties of the Carbolites seemed to be determined by the nature of the starting materials and the method of condensation. Acid condensing agents are reputed to yield resins of low resistance to chemical action.<sup>83</sup> Aniline, benzene, carbon disulphide, benzine, turpentine and sunflower oil have no effect on the Carbolites. Acetone makes them disintegrate into small insoluble flakes. Carbolites containing fatty acids are more highly resistant to nitric acid than the unmodified resins. Dilute sodium hydroxide solution attacks the Carbolites, but dissolves only a few per cent of the resin content.<sup>84</sup>

Tarasov and Shestakov<sup>85</sup> obtained infusible insoluble products by condensing phenols with formaldehyde in the presence of salts of sulphonic acids (naphtha sulphonic acids or the so-called sulpho-aromatic fatty acids which are formed

by sulphonating mixtures of fatty oils or olein and unsaturated hydrocarbons). An acid which does not decompose such salts was also present.

For example, 300 parts by weight of cresol were gradually mixed with 135 parts of a 40 per cent solution of sodium salts of "naphtha sulpho-acids," 9 parts of hydrochloric acid (sp.gr. 1.14), and 150 parts of 40 per cent aqueous formaldehyde, and heated to 65-70°C. A resinous liquid mass separated with a watery layer on top. The latter was removed and the resinous mass heated until there was a loss of 70-75 parts by weight of the total reactants used. After cooling to 35-45°C., 120 parts by weight of aqueous 40 per cent formaldehyde were added and the whole mixed to a homogeneous mobile liquid, which was poured into molds, cooled, kept for 1 hour at 45°C., and finally heated to 100°C.

Other sulphonated compounds besides sulphonated petroleum have been investigated as phenol-formaldehyde condensation catalysts. Long ago it was shown<sup>90</sup> that a mixture of sodium sulphite, formaldehyde and  $\alpha$ -naphthol yielded a crystalline hydroxynaphthylmethylsulphonic acid, but no mention was made of resinous by-products. Transparent infusible resins have been made<sup>91</sup> by condensing phenol with formaldehyde in the presence of naphthalene- $\alpha$ -sulphonic acid. In this case, glycerol and fusel oil were also incorporated, and the product was dehydrated *in vacuo*.

Pollak<sup>92</sup> used crystallized phenol, 18.8 parts, paraformaldehyde, 8.73 parts, and an aqueous solution of p-phenolsulphonic acid, 0.04 part. The mixture was warmed on a water bath and after completion of the reaction, the product was poured into molds in which, at about 100°C., it became hard and insoluble. If oxidation of the surface of the product was to be avoided, the process could be carried out in an inert gas, e.g., nitrogen, hydrogen or carbon dioxide. Before the reaction was completed and while the product was still in a soluble form, fillers or modifying agents could be added (asbestos, graphite, sand, powdered metals, tar, resins, oils, colors, cellulose, acetyl cellulose).

A self-hardening composition has been prepared by refluxing a commercial solution of formaldehyde (25-175 parts) with a phenol (210 parts). After cooling and removal of water, furfural (140 parts) was added along with 20-30 per cent of asbestos filler and 1-30 per cent of a product obtained by mixing 70 parts of concentrated sulphuric acid with 30 parts of ethyl alcohol.<sup>93</sup>

### SALTS

When salts are used as catalysts in phenol-formaldehyde condensations, their function is usually to control the course of the reaction by determining the hydrogen ion concentration. Accordingly, a mixture of zinc chloride and hydrochloric acid catalyzes the formation of products which are similar to those obtained by the use of hydrochloric acid alone.<sup>94</sup> In general, it appears that the nature of the resinous product is determined by the concentration of hydrogen ion,<sup>95</sup> and is largely independent of other ions which may be present during the reaction. It was early noted by Claypoole<sup>96</sup> that the resins formed from phenol and formaldehyde in the presence of sodium carbonate or sodium cresylate resembled those obtained through the use of sodium hydroxide. Story<sup>97</sup> had recorded the fact

that resins made in the presence of salts differed from those made in the absence of added catalysts in that the latter were transparent. These facts indicate that the degree of acidity or alkalinity is more important than any specific catalytic properties attributable to the salt itself. Sugimoto<sup>94</sup> noted that each of the different types of phenol-formaldehyde condensation products could be obtained through the use of hydrochloric acid as catalyst, provided conditions are carefully controlled. Measurement of hydrogen ion concentration is a convenient means of ascertaining whether or not conditions are proper for the desired type of resin formation. Thus, Jackson and Cameron<sup>95</sup> found that the initial stage of the condensation took place at a  $pH$  of 6.5-8.5. This  $pH$  was maintained by the use of (1) triethanolamine, (2) trisodium phosphate, (3) a mixture of trisodium phosphate and sodium hydroxide, (4) phthalic anhydride and sodium hydroxide, (5) sodium phthalate or (6) a mixture of borax and sodium hydroxide. Neutral inorganic salts are added to serve as anti-foaming agents. By buffering the reaction mixture in the manner indicated, a clear liquid resin was produced. It could be molded and cured at 85-125°C. Matsumoto<sup>96</sup> noted that each stage in the condensation of phenol and formaldehyde was associated with a certain optimum degree of acidity or alkalinity. He regarded the resin-forming process as taking place in 3 stages, viz, the initial condensation, the concentration of the products and the final hardening. The best results were obtained when sodium hydroxide and ammonia were used as condensing agent and hardening agent respectively. The condensation proceeded satisfactorily in the presence of sodium sulphite or sodium carbonate, but these salts were not suitable hardening agents.

Dior<sup>97</sup> chose as a catalyst the ammonium salt of a volatile acid, and carried out the condensation in the following manner. Formaldehyde (40 per cent), 3 gal., was added to commercial carboic acid, 5.5 gal., and ammonium bicarbonate, 6 lbs., in a steam-jacketed digester provided with a reflux condenser. The reaction began in the cold and was completed by heating to 50-100°C. for about  $\frac{3}{4}$ -1 hour. The apparatus was then cooled by passing water through the jacket. The upper aqueous layer was decanted, and the condensation product left for 2-3 hours, after which time it was partially dehydrated. Finally, the resin was heated at 110-120°C. *in vacuo* or under normal pressure until all traces of water and catalyst were removed. Jaloustre, Kheifetz and Warchavsky<sup>98</sup> produced an acid-resistant infusible resin by treating phenol with formaldehyde solution in the presence of sodium salicylate or ammonium thiocyanate, 5 per cent (of the weight of phenol) and sodium cyanide, 2 per cent. The liquid and soluble product was hardened by heating at 95-100°C. in an open vessel. Moss<sup>99</sup> reacted approximately equal molecular proportions of phenol and formaldehyde in the presence of dihydrogen phosphates. The reaction was initiated by the use of phosphoric acid, and then sufficient ammonium or sodium hydroxide was added to form the dihydrogen phosphate. Pale fusible resins which were soluble in acetone were obtained.

With respect to the use of sodium carbonate as a phenol-formaldehyde catalyst, certain points of interest may be mentioned. Lebach noted<sup>100</sup> that when this condensing agent was employed, carbon dioxide was expelled violently and the caustic alkali set free was effective in carrying out the condensation. An intermediate

<sup>100</sup> H. Lebach, *J.S.C.I.*, 1913, 32, 559.

formaldehyde-carbonic salt was assumed. The cresols condense satisfactorily with sodium carbonate, sodium alcoholate or sodium formate.<sup>101</sup> A mixture of sodium carbonate and water-glass was proposed by Regal.<sup>102</sup> He also recommended sodium aluminate, sodium zincate or aluminum acetate. Rolker used sodium carbonate enclosed in a small perforated aluminum container.<sup>103</sup> The container was suspended in the reaction mixture, and was withdrawn when a definite viscosity of the mixture was attained. In this way, the reaction could be arrested at any stage. Another suitable method of controlling the condensation when sodium carbonate was used as the catalyst was to add oxalic acid to the reaction mixture<sup>104</sup> before the gelation stage has been reached.

A phenol-formaldehyde resinous product<sup>105</sup> of low viscosity and high solubility was obtained by Actmeyer using sodium tungstate or a mixture of sodium tungstate and trisodium phosphate as catalyst. White condensation products resulted when the catalyst was a mixture consisting of a borate (ammonium or an alkali metal borate) and a salt of tin, titanium, antimony, magnesium or zinc.<sup>106</sup>

Condensation by the use of salts of aromatic hydroxy acids, such as hydroxybenzoic or tannic, has been proposed by Wennagel.<sup>107</sup> For example,<sup>108</sup> 100 parts of phenol, 80 parts of formaldehyde and 5-10 parts of a 50 per cent solution of sodium salicylate were mixed and heated until an exothermic reaction started. Upon completion of the reaction, the water contained in the initial materials was expelled by evaporation, and the mass heated in molds. The product at this stage was liquid, but when the molds had cooled to about 60-80°C. they could be opened, the resin being then thoroughly solidified. A period of 12 hours was sufficient for this operation. Salts of aliphatic hydroxy acids have also been employed as catalysts. La Croux<sup>109</sup> treated a phenol-formaldehyde mixture with calcium carbonate, and then neutralized the resulting product with lactic acid. Sodium thiosulphate was added to obtain white substances, highly resistant to alkalis. The addition of lithopone gave the resin an ivory, citric acid a mottled ivory and calcium chloride a mother-of-pearl appearance. Added lead salts rendered the resin impenetrable by X-rays. Titanium citrate, tartrate and lactate have been used as catalysts for the formation of phenol-formaldehyde resins.<sup>110</sup> Sato<sup>111</sup> prepared a liquid product from phenol and formaldehyde with sodium sulphide and 5 per cent of an hydroxy fatty acid, e.g., glycollic, malic, lactic, tartaric or citric acid.

Petrov<sup>112</sup> used salts of hydroxy acids in the following manner: The phenolic substance was heated under reduced pressure with only a portion of total quantity of formaldehyde necessary for the reaction. This was done in the presence of coal-tar or mineral oils, suggested proportions being 100 parts of phenol, 15 parts of coal-tar oil, 70 parts of 40 per cent aqueous formaldehyde, and 10 parts of barium phenolate in 10 parts of water. A thick, transparent substance was formed. This was heated at atmospheric pressure until the volatile matter was removed. Thirty parts of 40 per cent formaldehyde were mixed with 100 parts of the initial resin, the temperature being kept below

50°C. At this point an emulsifying agent consisting of the potassium salt of an hydroxy acid made by oxidizing a drying oil was added in quantity up to 10-15 per cent. As an alternative this salt could be replaced by sulphonated castor oil. Upon removal of water a resinous product said to have good dielectric properties was obtained.

Considerable attention has been given to the use of alkali phenolates as catalysts for phenol-formaldehyde condensations. In a process<sup>113</sup> described by Brown and Kendall, trioxymethylene was dissolved in anhydrous cresol, and a wire cage containing balls of calcium cresolate was suspended in the mixture. An exothermic reaction was initiated by the application of moderate heat. An intermediate product was first formed, and this was converted to a hard resin by heating at 82-99°C. for five to six hours. Mellanoff<sup>114</sup> employed an alkaline solution of peat as a condensing agent. Also, phenols have been condensed with formaldehyde in the presence of powdered lead or zinc.<sup>115</sup> Petrov prepared a condensation catalyst by concentrating phenolic solutions of alkaline earth metals in the presence of a small quantity of formaldehyde.<sup>116</sup>

Wennagel<sup>117</sup> used soaps, particularly the resinate, stearate, palmitate and oleate of potassium, sodium, aluminum or calcium in quantities greater than one-fifth of the weight of phenol. The resins thus made are said to be more elastic than those made with more conventional catalysts. Sodium stearate and sodium sebacate were used by Jäger<sup>118</sup> as catalysts in the preparation of resins resembling horn.

Sodium sulphite was early investigated<sup>119</sup> as a catalyst in phenol-formaldehyde condensations. An addition compound of sulphite and formaldehyde was formed, and probably took part in the reaction mechanism. Robinson-Bindley, Weller and Dulcken<sup>120</sup> condensed formaldehyde, or substances yielding it, with o-, m- or p-cresol in the presence of sodium sulphite. The process was carried out by vaporizing the cresol with steam, and passing the vapors with formaldehyde into a reaction chamber containing sodium sulphite at a temperature of 60-90°C., or, alternatively, the cresol could be heated to 60°C. and formaldehyde gas blown through it in the presence of the catalyst. The product was further hardened by heating at 60-100°C. at atmospheric pressure or by heating it at higher temperatures under pressure. Scudder and Pettigrew<sup>121</sup> obtained a thin liquid phenolic condensation product, adapted for use in the preparation of impregnants, by allowing sodium sulphite, 40 per cent formaldehyde and carbolic acid, in about the proportions of 50, 100 and 1000 parts by weight respectively, to react together for 3 or 4 days with occasional stirring. The supernatant aqueous layer was removed, and the lower layer, containing 55-56 per cent of resin, could be used for impregnating porous articles, which were dried at 80-90°C. and heated under pressure for final hardening. Similarly, condensation products were prepared<sup>122</sup> by heating  $\beta$ -naphthol with an aqueous solution of formaldehyde in the presence of sulphites and sodium hydroxide. Byrom<sup>123</sup> has investigated the use of sodium

thiosulphate in the manufacture of phenol-formaldehyde condensation products. A mixture of 112 lbs. of cresylic acid of 98 per cent purity and containing no sulphur compounds, 72 lbs. sodium thiosulphate and 16 lbs. of 40 per cent formaldehyde was heated to about 115°C. for 2 hours. Further quantities of 16 lbs. of 40 per cent formaldehyde were introduced at half-hour intervals until 64 lbs. had been added. As the condensation proceeded the product changed from a clear liquid to a plastic solid which was hardened by heating at 140-200°C.

Weindel<sup>124</sup> employed sodium hydrosulphite to restrain resinifications catalyzed by hydrochloric acid. Thus, 1000 parts phenol, 1000 parts 40 per cent aqueous formaldehyde and 10 parts hydrochloric acid of 24° Bé were heated together until a separation of oil occurred. Then 10 parts of sodium hydrosulphite were added, and the condensation was immediately arrested. The separated colorless oil thickened on cooling, forming a pasty plastic compound. To purify, the oil was stirred with cold or warm water, or steam was conducted into the mass. The product was soluble in alcohol and acetone and was proposed for use as a shellac substitute. In another example, twice as much hydrochloric acid was used, and, when the separation of oil had occurred, 17 parts of formaldehydesodiumsulphoxylate were added to arrest the reaction. On cooling, the condensation product was a white, opaque, plastic compound soluble in alcohol, acetone and ethyl acetate. When heated at 140°C. a resinous material was obtained. This was proposed for use as a shellac substitute. Smaller proportions of sodium hydrosulphite or formaldehydesodiumsulphoxylate gave insoluble products.

A large number of inorganic halides have been employed as phenol-formaldehyde catalysts. Zinc or aluminum chloride<sup>125</sup> gave a product which could be converted by means of acid into a resin said to be useful as a substitute for natural gums. Zirconium chloride also has been recommended.<sup>126</sup> Stockhausen and Grühl<sup>127</sup> kneaded a fluid phenolic condensation product at 30-50°C. with salts of trivalent metals (e.g., 50 per cent ferric chloride calculated on the phenol) and with sulphur, rubber or filling materials. After separation of water, the mass was heated and an infusible insoluble product was obtained. In preparing an initial condensation product the reaction could be interrupted at the point of incipient turbidity by sudden cooling. Plastic masses which were kneadable in the cold were made by condensing phenol with formaldehyde in the presence of alkaline earth chlorides, notably calcium chloride.<sup>128</sup> These plastics could be molded and thermally hardened. They were also adapted for incorporation in varnishes. When stannous chloride was used<sup>129</sup> as a condensing agent, the reaction was so energetic that it was necessary to cool the mixture at the beginning. No such reaction was noted when stannic chloride was used. Sato and Sekine<sup>130</sup> observed that copper carbonate, stannic chloride, ferric chloride and potassium ferrocyanide reacted with all types of phenol-formaldehyde resins. Color reactions were obtained with the insoluble infusible type. Schmidt<sup>131</sup> hardened the condensation products resulting from phenol-formaldehyde by treating with as small a quantity as possible of acid. Sufficient acid was provided by the hydrolysis of ethylenechlorohydrin or magnesium chloride. Plasticizers and clarifiers were also included in the final product, which was non-adhesive and suitable for cold-pressing

followed by thermal hardening. Weindel<sup>132</sup> similarly catalyzed phenol-formaldehyde condensations by means of chlorohydrins. Mannesmann<sup>133</sup> proposed sodium bromide or potassium bromide as catalysts for the condensation of cresol with formaldehyde. Sato<sup>134</sup> used copper sulphate, nickel sulphate, zinc chloride and calcium chloride for the conversion of liquid condensation products into hardened resins. Sulphuryl chloride, sulphur chloride, phosphorus oxychloride, acetyl chloride and benzyl chloride have been suggested as condensation catalysts by Matheson.<sup>135</sup> Phosphorus pentachloride has also been recommended.<sup>136</sup> The products obtained by the action of sulphur chloride on fatty oils (factice) were used by Buser.<sup>137</sup>

Various investigators have prepared resins from phenol and formaldehyde by the use of ammonium chloride as catalyst. For instance, in a process described by Hutin and Dauphin<sup>138</sup> 1 part of formaldehyde was mixed with 1 part of phenol (crude, synthetic). To this mixture was added one-quarter part of the residue obtained in the manufacture of synthetic phenol, 0.5-1 part water and 0.1 part of ammonium chloride. The reaction mixture was allowed to stand for several hours. Fillers were then added and the product molded in a heated press.

A translucent resin said to be useful in the preparation of an odorless varnish was made by reacting phenol with formaldehyde in the presence of ammonia, sulphuric acid or triethanolamine and calcium bromide. The initial product was dissolved in alkali and then reprecipitated with acid. A resin which could be washed, dried and dissolved in varnish solvents was obtained.<sup>139</sup>

A number of salts other than those mentioned above have been used as catalysts for the phenol-formaldehyde condensation. For instance, an insoluble infusible resin of dark garnet color was made by the use of sodium cyanide<sup>140</sup> as condensing agent. Sodium cyanide forms an intermediate substance recalling the aldehyde-bisulphite compounds.<sup>141</sup> In the presence of lead acetate, condensation of phenol with formaldehyde leads to formation of Novolaks, as might be expected because of the acidic nature of the reaction mixture.<sup>142</sup> Metal carbides, silicides or phosphides have been used by Nuttall<sup>143</sup> to catalyze the final stages of the condensation. The initial stages were catalyzed by ammonium chloride, sodamide, metal alcoholates or the compounds of ammonia with zinc or calcium chloride.

#### HALOGENS, OZONE AND SIMILAR CATALYSTS

Chlorine has been used as a catalyst in phenol-formaldehyde condensations.<sup>144</sup> In one instance phenol was heated first with a portion of the required amount of formaldehyde in the presence of chlorine and then with the remainder of the formaldehyde in the presence of sodium nitrate. After the reaction stopped, a further heating to a temperature above 120°C. followed. For example, formaldehyde (40 per cent solution), 34 parts, and crystallized phenol, 46 parts, were allowed to condense at 45-55°C. with 0.8 part of chlorine, and when the liquid be-

<sup>144</sup> German P. 273,261, 1912, to Allgemeine Elektrizitäts-Ges.; *Chem. Abs.*, 1914, 8, 2817.

came somewhat gelatinous, 20 parts of formaldehyde solution and 0.5 part of sodium nitrate were added. After several hours the temperature was increased gradually to 70-80°C. until a viscous transparent strongly glutinous product was obtained. The completely dried product was reddish brown. By heating to over 120°C. it became infusible. Petrov<sup>145</sup> employed the sodium salt of toluenesulphonchloramide (Chloramine T) in catalyzing phenolic condensations. A mixture of 100 parts of phenol, 100 parts 40 per cent formalin and 2 parts toluenesulphonchloramide was heated until a viscous varnish-like mass separated. This material was soluble in varnish solvents and could be converted into an insoluble infusible resin by the application of heat.

Ozone, sandarac ozonide and pinene ozonide were found to catalyze the formation of phenol-aldehyde condensation products.<sup>146</sup> The decomposition products of ozonides also serve this purpose.<sup>147</sup> Ozonized formaldehyde likewise may be used,<sup>148</sup> the condensation being of the type taking place in the presence of acids. Phenolic resins are polymerized by the action of long wave-length radiations obtained from mercury vapor lamps.<sup>149</sup>

Seebach<sup>150</sup> found that Novolaks could be hardened by treating them with chloranil,  $C_6Cl_4O_2$ , or with a quinone. For instance, he mixed 90 parts Novolak, 10 parts quinone and 100 parts filler in a ball-mill. No volatile substances were formed, a circumstance which was quoted as an advantage possessed by this type of hardening agent.

## Chapter 17

### Phenol-Aldehyde Resins

#### V. Employment of Other Phenols

During the early growth of the phenol-aldehyde resin industry from 1907 to 1914, there was considerable restlessness, on the part of the limited number of manufacturers, with regard to phenol as a raw material. Commercially this feeling was justified. The world production of phenol was not large. Germany and England were the principal producers, and the only ones sufficiently large to export any. In the United States, production was very small and limited to a sole producer, whose product was used almost entirely for medicinal purposes. A certain amount was annually imported to provide the supply required in excess of domestic production. It is true that the potential production of this country was quite large, but it was scattered over a large area and the manufacturers were loath to compete with imported supplies.

There was a greater domestic production of cresols, and, moreover, these could be produced more cheaply. Speaking in relative terms phenol sold for 8 cents a pound, now and then on war scares and plagues or pestilence rising to 10 or 10½ cents. Cresylic acid, which was on the market, consisted of a mixture of the three isomeric cresols, ortho, meta and para, with small amounts of xylenols. In price it ranged from 5¼-8¼ cents per pound. The only difficulty was in the o-cresol content. That could be removed (at least, in part) by distillation<sup>1</sup> and used for disinfectant purposes. There was no sizeable production of other phenolic bodies. However, a great deal of experimental data on possible substitutes for coal-tar phenol were available.

The advent of the World War changed conditions materially. Imports of phenol were largely shut off and prices soared. The forehanded manufacturer, who had been able to lay in supplies, made large sums on the increase in value. Those with insufficient capital and poor sources of supply were very badly handicapped indeed. The production of synthetic phenol was commenced in this country, and though its first use was entirely for munitions purposes, its later developments had an important bearing on the resin industry. The tremendous demand for toluene expanded all phases of tar products recovery and supplies increased.

After the cessation of hostilities enormous supplies of unused phenol were on hand. Large plants for the production of synthetic phenol were idle and their owners had either to run them in competition with government-owned phenol, sold on a commission basis, or cease production. A few survived, and since that time there has always been an ample supply of relatively cheap phenol. Concurrently the expansion of the coal-tar industry has continued and the so-called natural phenols and cresols are in plentiful production.

<sup>1</sup> F. Ullmann, *Enzyklopädie der technischen Chemie*, Urban u. Schwarzenberg, Berlin, 1919, 7, 254. J. Scheiber, *Angew. Chem.*, 1933, 46, 503; *Chem. Abs.*, 1933, 27, 4975. H. Brückner, *Erdöl u. Teer*, 1928, 4, 580; *Chem. Abs.*, 1929, 23, 1246.

Shortly after this the early patents on Bakelite resins began to expire and the second era of the industry may be said to have begun. In this latter period the search has not been so much for cheaper replacements as for materials that would give different properties to the resultant resins.

#### RESINS FROM PHENOLIC TARs

Perhaps resins which occur during the coking of coal should be called natural resins. They do not occur in nature, as do the fossil resins, but they arise on treating coal with heat for the purpose of making coke. Trade custom has given the name of natural phenol to phenol extracted from coal-tar, in contrast to phenol made by sulphonation of benzene and fusion with caustic alkali, or by the more modern chlorination process. By analogy, resinous products from coal-tar are sometimes considered as natural resins.

In the past, when coking operations in this country were limited to city gas plants, coal-tar distillers concerned themselves largely in the production of creosote oils and pitch. Following the introduction of coke-ovens, an advance was made in that benzol began to be recovered. H. W. Jayne of Philadelphia, handicapped by unrestricted foreign competition, developed the production of benzene, toluene, xylene, naphthalene, phenol, cresol and other related chemicals.

As soon as tar began to be split into more than two simple components it was noticed that reddish resinous compounds could be obtained near the end of the distillation. These were collected and some attempts were made to study them. No published data of these studies exist, unfortunately. As the coal-tar industry grew, hard pitch at times accumulated to such an extent that attempts were made to subject it to further distillation to form pitch coke, a material in demand for the production of electrodes on account of its very low ash content. This further coking operation yielded considerable quantities of resinous bodies and at infrequent intervals they were studied in a desultory manner. Publication was again avoided and no results negative or otherwise are available.

Weiss<sup>a</sup> obtained by the destructive distillation of coal tar or coal-tar pitch a semisolid or solid bitumen stated to be suitable for waterproofing, molding, luting or use as a shoe filler. He also suggests mixing the bitumen with fibrous materials or other fillers and pigments. This same resinous material may be<sup>a</sup> incorporated with rubber to form electrical insulators or waterproofing compositions. A material proposed for use in paints or on roads is formed<sup>a</sup> when 80 parts of coal-tar pitch, 20 parts of petroleum naphtha and 1-3 parts of "tar acids" are mixed together. Resinous materials from coal tar according to Bailey and Boettner<sup>b</sup> may be employed, after purification by washing with 12 per cent of toluene, for mixing with other resins such as cumarone, indene or halowax resins, or such substances as sulphur, rosin, montan wax or carnauba wax. They may be used in varnish, rubber mixtures or waterproofing materials. The same investigators<sup>a</sup> proposed a waterproof composition to be made from "pitch resin" in the following proportions: resin 2.5, paraffin or wax 0.07, coal-tar naphtha 7.5 and high boiling tar acids 0.025 parts. They state that it is adapted to use on canvas or other fabrics.

Tars, because of their abundance and cheapness, their broad distribution, numerous points of production and usual phenolic content have been studied to a considerable extent as possible raw materials for resins of the phenol-aldehyde class. For such a use it is desirable that the properties and, if possible, the com-

<sup>d</sup> G. C. Bailey and F. Boettner, U. S. P. 1,355,103, Oct. 5, 1920; *Chem. Abs.*, 1921, 15, 166.

<sup>e</sup> G. C. Bailey and F. Boettner, U. S. P. 1,364,475, Jan. 4, 1921; *Chem. Abs.*, 1921, 15, 762.

position of the phenolic mixture be known. A great deal of work has been done on the composition of coal-tars,<sup>7</sup> and many methods have been worked out for the isolation or preparation of phenolic bodies from them. For example, p-xyleneol (2,4-dimethylphenol) can be obtained from the fraction boiling at 210-212°C. by treating the crude material with 0.2 part of sulphuric acid at 40°C. for 5 hours, and fractionally crystallizing the salt obtained by neutralization with ammonia. Hydrolysis of this salt gives p-xyleneol.<sup>8</sup> Among the compounds which have been obtained from coal-tar are phenol, the 3 cresols, 5 of the 6 xyleneols, 3-methyl-5-ethylphenol and 2,3,6-trimethylphenol.

Phenols of higher molecular weight than the xyleneols constitute approximately 66 per cent of the tar acids of low-temperature tar. The presence of aliphatic side-chains in these compounds is indicated by a decrease in specific gravity with increase in boiling point. As the boiling point rises further, this decrease in density gives way to a sharp increase, corresponding to the appearance of  $\alpha$ - and  $\beta$ -naphthols. Fractions of minimum density are collected at 234°C., and consist largely of 3-methyl-5-ethylphenol. Other simple alkylated phenols are collected up to 260°C.<sup>9</sup> In these compounds alkyl groups are located usually in the meta position to the hydroxyl. The chemical identity of many of the constituents<sup>10</sup> still remains in doubt. More subtle questions as to the nature of these materials are raised by the observation that intramolecular changes can occur between the hydrogen of a phenolic hydroxyl group, and various groups substituted in the ortho or para position.<sup>11</sup>

The use of tarry fractions for making phenol-formaldehyde resins usually involves some preliminary refining treatment. In the crude tars impurities are present which either catalytically affect the formation of resin, or give the product an objectionable texture. Ammonium salts and nitrogen bases are removed by washing the tar with water or dilute acid.<sup>12</sup> Sulphur compounds (mercaptans, thiophenols) and organic compounds of iron and aluminum are likewise objectionable, and are removable by fractional steam-distillation.<sup>13</sup>

Morgan carried out the purification and decolorization of phenols or neutral tar oils by heating them at 100°C. with 1 per cent formaldehyde in the presence of an acid or alkaline catalyst, and then distilling the product.<sup>14</sup> By treating acid tars at 80-160°C. under atmospheric or increased pressure<sup>15</sup> with aldehyde, and in the presence of phenols and condensing agents such as sulphuric or hydrochloric acid, it is possible to extract constituents with organic solvents, which are suitable for use in the manufacture of lacquers or plastic compositions. Sawdust can be added to the acid tar before reaction or it can be impregnated with the extracts of the condensation product, and mixed subsequently with the insoluble extraction residue. Karpati<sup>16</sup> devised a process for working up tar oils by converting the phenolic constituents into non-volatile condensation products by treat-

ment with concentrated sulphuric acid or with formaldehyde. When concentrated sulphuric acid is used, residues capable of being used as tanning agents are obtained. Treatment with formaldehyde gives resinous condensation products of the phenol-aldehyde type. The neutral oil is separated from these by distillation in a current of superheated steam.

Another method<sup>17</sup> of getting rid of the neutral constituents of the coal-tar (b. p. up to 300°C.) before reaction with formaldehyde is to extract the tar with caustic alkali, and use the alkaline solution of phenolates for reaction with formalin or hexamethylenetetramine. The condensation is carried out at about 100°C. Excess alkali is neutralized with dilute sulphuric acid or by passing carbon dioxide (or flue gases) into the mixture. A granular resin is precipitated, and can be filtered, washed, dried, softened by heat, molded at high pressure and heat-hardened.

When the impurities in crude tar oil do not affect the rate of reaction of resin formation, but confer detrimental properties on the product, it is possible to treat the resin for the removal of undesirable constituents. A phenol-aldehyde resin is prepared by heating a coal tar fraction (b. p. 170-230°C.) with paraldehyde in the presence of pyridine, and extracting the product with warm benzene until the washings are colorless.<sup>18</sup> Final purification is accomplished by vacuum distillation with denatured alcohol. The paraldehyde may be replaced by formalin, pyridine by other bases and benzene by carbon tetrachloride or light oils.<sup>19</sup> The resins thus prepared were used in making single impregnated sheets and laminated boards, and the dielectric properties of the products were investigated. Resins from pure and crude phenol and two commercial resins were also tested for comparison. The tests showed that the mixed phenols of low-temperature tar are utilizable in the preparation of resins of high dielectric strength. The phenolic resins prepared as above have also been suggested for protecting wool against fungi<sup>20</sup> and for varnishes. Varnishes prepared from these resins darken on exposure but when mixed with aluminum powders, little darkening takes place. The tar resins furnish wood stains of even tone without raising the grain of the wood. It is customary to carry out the condensation of formaldehyde with phenolic tars in the presence of hydrocarbon oils, which occur in the tar or may be added to it for the purpose of thinning those already present. After the resin has formed, the mixture separates into three distinct layers, the main constituents of the several phases being, respectively, resin, water and hydrocarbon. Caplan<sup>21</sup> recovered the resins remaining in the hydrocarbon oil layer by adding a solvent for the oil in which the resinous condensation product is substantially insoluble, such solvents being petroleum ether, carbon tetrachloride or ether. Bhagwat<sup>22</sup> found that dilute mineral acid, such as hydrochloric or sulphuric acid, can be used to effect the separation. By shaking 1000 cc. of the hydrocarbon oil residue containing unrecovered resins with 150 cc. of 15 per cent hydrochloric acid, the resins separated as a deposit at the bottom, the purified oil collected in a layer at the top, while the acid solution remained in the middle layer.

The condensation of formaldehyde with phenolic tars can be carried out in the presence of a wide variety of catalysts other than those already mentioned. Tars were made more adaptable for road construction and roofing, according to Broad-

head and Andrews,<sup>23</sup> by heating in the presence of an aldehyde and a catalyst such as ammonia or ammonium sulphate to not over 100°C. in a closed vessel and then adding a catalyst such as ferrous sulphate and raising the temperature to 100-200°C. and passing air through the digested materials. Glud and Breuer<sup>24</sup> have made a study of the reaction between formaldehyde and various phenolic tars derived by low-temperature carbonization. Soluble, fusible resins were obtained from these phenols by treatment with formaldehyde using ammonium chloride as a catalyst. Crude tar oils containing phenols were condensed by heating with formaldehyde in the presence of such catalysts as sodium hydroxide, sulphuric acid, ammonia, ammonium chloride or benzylamine.<sup>25</sup> The resinous condensation products were separated from the neutral oil residue by steam distillation under reduced pressure. Hydrocarbons did not interfere with the resinification. Crude tar fractions boiling between 150-250°C. and also between 250-300°C. including the hydrocarbons that distil at these temperatures were used. Beutner and Hessen<sup>26</sup> treat phenolic tar oils (b. p. below 205°C.) with formaldehyde in the presence of alkaline condensing agents. Hydrocarbons or chlorinated hydrocarbons which are miscible with the neutral constituents of the tar, but which are not resin solvents, are added to assist the separation of the resin. Beutner<sup>27</sup> treated a coal-tar oil with formaldehyde, aqueous sodium hydroxide solution, and kerosene to yield a product which separates into three layers.

Thus, he heated 200 parts of 25 per cent tar acid oil, 40 parts of commercial kerosene, 80 parts of 40 per cent formaldehyde solution and 25 parts of a normal sodium hydroxide solution for ½ hour under reflux. After separation, the top layer consists of 190 parts of hydrocarbons, 85 parts of an aqueous layer are in the center and 75 parts of a resinous layer are at the bottom. The bottom layer can be heated to transform it into a soluble fusible resin or it can be heated beyond this to obtain an infusible insoluble resin. The condensation of a coal-tar oil distilling above 224°C. and preferably below 300°C. with aldehydes and ketones in the presence of alkaline catalysts has been investigated by Terwilliger.<sup>28</sup> For example, 100 parts of coal-tar oil boiling between 224 and 300°C., 30 parts of acetone, 50 parts of paraformaldehyde and 3 parts of sodium or potassium hydroxide are heated to effect condensation. The resin obtained may be used in a solvent as a baking varnish or it may be hardened by further heating to the infusible insoluble stage. Other ketones or other aldehydes (e.g., furfural) may be used.

Burke<sup>29</sup> produces a moldable and heat-hardenable synthetic resin by reacting a mixture of primary tar acids and unsaturated hydroaromatic hydrocarbons, with formaldehyde, in the presence of an alkaline condensing agent stronger than ammonia. One volume of 40 per cent formaldehyde solution, 3 volumes of tar oil (distilling 200-300°C.) and 2-10 per cent by weight of sodium carbonate solution are the proportions he suggests. The mixture, after heating and reacting until no tar acids remain in the oil, separates into layers, the fusible resin settling on the bottom.

The rate of reaction of crude tar with formaldehyde in the presence of alkali is sometimes difficult to control, and accordingly there is danger of premature setting in the reaction kettle. One way of averting this is to neutralize the alkali in the reaction mixture at an early stage in the resin-forming reaction.<sup>30</sup> If lime is used as the alkaline condensing agent, neutralization with sulphuric acid is effected as soon as one mol of formaldehyde has combined with one mol of phenol. The precipitated calcium sulphate acts as a filler. Since the original catalyst has been rendered useless by the neutralization, it is thereafter necessary to substitute another catalyst, ammonia, by means of which the rate of resin formation can be controlled. Another method of controlling the reaction is to check the polymerization by the addition of alcohol or a mixture of alcohol and benzene soon after the initial condensation has taken place.<sup>31</sup> Caplan<sup>32</sup> employed the tar acid content of coal-tars for manufacture of a resin in the following manner.

A tar distillate comprising the entire fraction up to 300°C. was mixed with formaldehyde and a normal sodium hydroxide solution in the following proportions. 300 l. tar distillate (32 per cent tar acids by volume), 87.5 kg formalin and 20 l. sodium hydroxide. The mixture was heated in a kettle under a reflux condenser, agitated and maintained at a boil for 45 minutes. The heating was then discontinued and 600 l. of petroleum naphtha and 200 l. of water were added. The mixture was again agitated for a few minutes and then allowed to settle. Three sharply defined layers were formed. The bottom layer was withdrawn and heated rapidly under vacuum to a resinifying temperature, about 96°C. After occluded water and naphtha in the resin layer were distilled off, the temperature was allowed to rise to 105°C. and maintained there until the resin had suitably thickened. The product was drawn off and allowed to cool and harden. It was a potentially-reactive resin, capable of hardening when heated to 180°C. The purpose of the petroleum naphtha was stated to be for the prevention of portions of the resin remaining in the tar oil, either dissolved or suspended.

Resins prepared from the phenolic fraction of Baltic shale oil are described by Brodskii.<sup>33</sup> The best results were secured by reacting the phenols (derived by extraction of this fraction with a 10 per cent solution of sodium hydroxide) with formaldehyde. The fraction boiling between 170-320°C. can also be used directly but gives only a 25 per cent yield of resin. Artificial shellac or synthetic varnish resins are obtained by Harrison<sup>34</sup> by treating phenolic oils (obtained by destructive distillation of xanthorrhoea gum) with formaldehyde in the presence of an acid catalyst.

Gluud and Breuer<sup>35</sup> investigated the formation of resins not only from crude tar (*vide supra*) but also from a number of the phenolic compounds which can be obtained from this tar. Thus, cresols were treated with benzaldehyde in the presence of a small amount of ammonium chloride, the temperature being about 120°C., and the time of reaction 7 hours. The product was a thick viscous dark brown material which was soluble in alcohol and benzol. When heated at 170°C. under a pressure of 10 atmospheres a transparent dark-red hard resin resulted which, however, was easily fusible and was soluble in alcohol or aqueous alkali. In another experiment, 50 g. cresols, 66 g. paraldehyde and 2 g. ammonium chloride were heated several hours. Only 17 g. of a dark semi-solid mass, soluble in alcohol or benzene, was obtained. Soluble products also resulted when the phenols of low-temperature tar were condensed with formaldehyde. An investigation of vari-

ous types of phenolic bodies by carrying out condensation with formaldehyde in the presence of benzylamine was also made by Gluud and Breuer. In this case the reaction was carried to the final stage by heating under pressure in a "bakelizer" (see Fig. 57). In general the procedure employed was as follows.

Proportions of phenol and formaldehyde (30 per cent strength) to correspond to 1 mol each were mixed and heated to boiling under a reflux condenser. One-fifth of a mol of benzylamine was added and a violent reaction ensued. The heating was continued for 0.5-1.5 hours, then the reaction mass was cooled with ice and the aqueous layer removed. Exposure to the heat of the water bath caused the opaque resinous material to become clear. The heat treatment in the bakelizer consisted in exposing in an atmosphere of carbon dioxide at 100°C. under a pressure of 1.5 atmospheres. The carbon dioxide was allowed to flow through the bakelizer and the exit gases were noted to smell strongly of phenol. The temperature was gradually raised and at the end of one hour reached approximately 170°C. The carbon dioxide pressure was increased to 10 atmospheres, which pressure was maintained for 2 hours. Finally, the pressure was increased to about 15 atmospheres. When cold the products were very hard, clear, glass-like resins free from bubbles, infusible and insoluble in common solvents. They were found to be indifferent to alkalis and most acids.

Potentially reactive condensation products were made by Romieux<sup>36</sup> by reacting a mixture of phenols, boiling above 202°C., with formaldehyde in the presence of less than 0.1 per cent alkali based on the phenol present. One hundred parts of crude cresylic acid, boiling from 209-223°C., and 24.5 parts paraformaldehyde, or its equivalent of formaldehyde solution, are heated under reflux in the presence of 0.03 part of sodium hydroxide for 1.5 hours. The two layers are separated and the resinous portion is boiled to expel water and increase the viscosity. The resin can be hardened in a mold, or it may be mixed with fillers and molded. It is stated that molded objects made from this resin may be ejected from the press while still hot without danger of the surface blistering. Mursch<sup>37</sup> mixed dry fiber such as paper or rag material with cresylic acid, formaldehyde and caustic soda in the presence of water and boiled the mixture to form a doughlike plastic. Novak<sup>38</sup> prepared an impregnating compound by condensing cresylic acid with formaldehyde, in the presence of 1 mol of ammonia for every 4 mols of cresylic acid, mixing the condensation product with tung oil and heating the mixture until it was sufficiently clarified to remain limpid when cool. Any excess of the cresol is removed by adding hexamethylenetetramine or polymerized formaldehyde. Lignin cresol resins have been proposed for molding materials. Fischer, Horn and Küster suggested<sup>39</sup> replacing the lignin by lignite or lignitic brown coal. Pulverized lignite, vacuum dried, is kneaded at 80°C. with 12 per cent cresol in a volatile solvent, which is removed by vacuum distillation. At the end of the reaction the material is subjected to a pressure of 300 kg. per sq. cm. at 150°C. They state it is stable, odorless, nonmelting, and its raw materials cost 1/10 of the cost of phenol-formaldehyde ingredients. Molding compositions can be made by impregnating fillers with the condensation product obtained by treating an alkaline solution of peat with a mixture of formaldehyde and phenol.<sup>40</sup>

Coniferous wood tar, saponified with concentrated alkalis, separated from the unsaponifiable matter and warmed with formaldehyde yields a viscous product. This is separated from the aqueous portion, washed repeatedly with water and dried. A hard, transparent, brown resin is obtained which is soluble in naphtha,

and the solution is used, mixed with mineral colors, as a paint.<sup>41</sup> Lingner<sup>42</sup> condensed "vegetable tar" with 40 per cent formaldehyde solution by the aid of hydrochloric or sulphuric acid. The resulting solid mass was dissolved in alkali and reprecipitated by dilute acids several times, then washed, dried and powdered. The product is claimed to possess all the medicinal properties of the original tar, but has the advantage of being practically odorless.

### CRESOLS AND XYLENOLS

In addition to the cresylic acids of commerce, which are usually mixtures of the three isomers, ortho, meta and para, there are fractions of tar acids containing substantial amounts of xyenols. These are known as high-boiling tar acids, or simply as H.B. Tar acid. Their main use is for the preparation of high-phenol-coefficient disinfectants, but they have attracted some attention as a source of phenol replacements. The melting and boiling points<sup>43</sup> of the cresols and xylenols and a few other homologues are given in Table 27.

TABLE 27—*Melting and Boiling Points of Various Phenols*

Type of Phenol		Melting Point	Boiling Point
Phenol		42.5°C.	181.5°C.
o-Cresol	2-methylphenol	30	190.8
m-Cresol	3-methylphenol	4	202.8
p-Cresol	4-methylphenol	36	201.5
2,3-Xylenol	2,3-dimethylphenol	75	218
2,4-Xylenol	2,4-dimethylphenol	26	211.5
2,5-Xylenol	2,5-dimethylphenol	74.5	211.5
2,6-Xylenol	2,6-dimethylphenol	49	212
3,4-Xylenol	3,4-dimethylphenol	65	225
3,5-Xylenol (symmetrical)	3,5-dimethylphenol	63.2	220.2
o-Ethylphenol	2-ethylphenol	-18	206.5-7.5
m-Ethylphenol	3-ethylphenol	-4	217
p-Ethylphenol	4-ethylphenol	46	218.5-9
Symmetrical methylethylphenol	3-methyl-5-ethylphenol	55	232.5-4.5
Isopseudocumenol	2,3,5-trimethylphenol	95-6	233
Mesitol	2,4,6-trimethylphenol	68-9	219.5
Pseudocumenol	2,4,5-trimethylphenol	71-2	234-5

The reactive positions in these compounds are ortho and para to the hydroxyl groups (see Chapter 14). Introduction of an alkyl group in the ortho position tends to reduce the reactivity of the para hydrogen, but meta substituting alkyl groups enhance this reactivity. The relative rates of condensation of substituted phenols with formaldehyde apparently parallel the reactivity series obtained by Hodgson and Jenkinson, who compared the rates at which various substituted phenols reacted in the Reimer-Tiemann reaction.<sup>44</sup> Symmetrical xylenol (3,5-dimethylphenol), which has three reactive hydrogens (2 ortho and 1 para) reacts with formaldehyde faster than phenol or m-cresol. It is of interest to note that m-cresol polymerizes with formaldehyde to a greater extent than does phenol.<sup>45</sup>

The rate of cure of resins made from cresols or xylenols is influenced by the

positions of the alkyl groups. Resins from o-cresol cure very slowly, and accordingly it is an undesirable constituent of resin-forming tars. o-Cresol may be detected by means of viscosity measurements.<sup>46</sup>

Though o-cresol has the disadvantage noted, uses for it in the preparation of resins have been proposed. To illustrate,<sup>47</sup> o-cresol was heated for several hours at 100°C. with formaldehyde, or substances capable of producing it, in the presence of acids, and the cooled mass was washed with water and purified by treatment with steam. The resultant product was a hard resin, varying in color from yellow to light brown, and melting at about 110-128°C. It was soluble in methyl and ethyl alcohols, dilute caustic alkali solutions, acetone, ether, carbon disulphide and chloroform; less soluble in benzol, chlorohydrin, carbon tetrachloride, turpentine oil and fatty oils. It served as a substitute for shellac and yielded varnishes which dry well on wood or metal. The hardness of the product depended upon the proportion of formaldehyde used. Ellis<sup>48</sup> described a composition containing an o-cresol-formaldehyde resin mixed with tung oil and asbestos. The particles of this mixture could be welded together by means of high pressure, without the application of heat. By condensing o-cresol (100 parts) and formaldehyde (70 parts 40 per cent solution) with acids (5 parts concentrated hydrochloric acid and 60 parts water), Gentsch<sup>49</sup> obtained straw yellow to light brown resins melting at 110-120°C. which were soluble in dilute alkalies, alcohol, acetone and chloroform. They were sparingly soluble in benzene and carbon tetrachloride, but insoluble in linseed oil and turpentine. Such resins, he states, furnish an odorless coating which dries well when used in varnishes or polishes.

Both o- and p-cresol tend to form permanently fusible and soluble resins of the saliretin type.<sup>50</sup> o-Cresol is considered particularly undesirable in making resins for molding compositions which have to be hardened in the mold. Baekeland, however, sought to utilize this relative inactivity in the production of resins which could be used as plasticizing agents. While it is true that infusible products may be obtained from o- and p-cresol, their production involves a length of heating which would be out of the question in any commercial molding operation requiring hot pressing. An infusible product may be prepared according to Baekeland when p-cresol reacts upon formaldehyde present in sufficient proportions, provided caustic soda is used as the condensing agent. If hydrochloric acid is used the product is more or less fusible and brittle. Similar proportions of formaldehyde reacting on phenol or m-cresol would result in infusible products. From o-cresol Baekeland has prepared a series of resins which are used to retard the time of final hardening in molding compositions made essentially from phenol or m-cresol and formaldehyde. He also described methods of making several varieties of infusible resin from o-cresol. A typical example is as follows:

One hundred g. o-cresol, 64 g. formaldehyde solution (40 per cent) and 1.6 cc. of concentrated hydrochloric acid were boiled for about 2 hours, then evaporated and heated to 200°C. A fusible resin of the saliretin type resulted. This was mixed with about 7-15 per cent by weight of paraform, and heated for 24-48 hours in a mold at a pressure of 45-90 lbs. The product was hard and infusible.

Aylsworth<sup>51</sup> prepared an oil-soluble cresol resin by heating together o-cresol, 30 parts, and a 40 per cent solution of formaldehyde, 14-16 parts, with a small amount of water. The water is not necessary but it decreases the violence of the

reaction. The amount added may be as much as 8 parts. Heating is done in an autoclave at 130°C. Excess of cresol and water are removed by vacuum distillation. The resulting resin melts at 60-77°C., and contains under 4 per cent of cresol. The formaldehyde is all combined and the resin is soluble in varnish oils and solvents. Berend<sup>52</sup> produced soluble fusible resins insoluble in linseed oil by reacting crude cresol with sufficient formaldehyde to combine with the m-cresol. The uncombined cresols were recovered from the mixture by vacuum distillation. Robinson-Bindley, Weller and Dulcken<sup>53</sup> prepared an oil-soluble product by condensing 50 parts of p-cresol with 70 parts of 40 per cent formaldehyde solution. Five parts of hydrochloric acid of 30 per cent strength constituted the catalyst. Oil-soluble resinous condensation products also are obtained from phenolic lignite-tar oils or low-temperature coal-tar oils by condensation with not more than a molecular proportion of acetaldehyde or higher aldehydes. Mixtures of acetaldehyde and higher aldehydes likewise may be used.<sup>54</sup> The addition of these oil-soluble resins to phenol-formaldehyde resins which are insoluble in oil is stated to confer solubility upon the phenol-formaldehyde resins. Subsequent treatment of the oil-soluble resins with formaldehyde converts them into products which are insoluble in oil.<sup>55</sup> A comparison of the resin from pure m-cresol<sup>56</sup> with products made from mixtures of cresol isomers indicates that the presence of o- and p-cresol has a softening effect. It has been reported that the best results are obtained when the m-cresol content is 60-70 per cent.<sup>57</sup> By boiling commercial cresylic acid of 97-99 per cent purity with such a proportion of 40 per cent formaldehyde solution that the mixture contains more than one molecule of formaldehyde for each molecule of cresylic acid and continuing the boiling until the solids determined at a temperature of 110°C. equal at least 40 per cent of the product, Handy<sup>58</sup> produced a resin which was infusible, hard, tough and insoluble in acetone. The final boiling, during which water and formaldehyde are distilled off, was conducted at a temperature of 110-120°C. The product obtained by this method was reported to be suitable for use as a binder in making brushes and for various other purposes. Compositions for use in brake-linings may be made by reacting cresylic acid and not more than 58 per cent (based on cresylic acid) of a 40 per cent formaldehyde solution.<sup>59</sup> A paint or enamel is prepared by Ornstein<sup>60</sup> as follows:

A solution of cresol 100, sodium hydroxide 6, water 94 and 40 per cent formaldehyde 75, after standing 12 hours, is mixed with a 10 per cent hydrochloric acid solution 100 parts, and the product allowed to settle to obtain an oily layer. A second solution of cresol 100, sodium hydroxide 6, water 94 and 40 per cent formaldehyde 60 parts, is heated to boiling and 15 parts formaldehyde and a 10 per cent hydrochloric acid solution are added, also producing an oily layer. The two oils are mixed, and solvents and pigments added to form paints. A small quantity of a chloride, nitrate or sulphate may be added to promote hardening.

Transparent condensation products from a mixture of equimolecular quantities of purified cresol or phenol and 40 per cent aqueous formaldehyde with 0.5 per cent alkali hydroxide as catalyst are prepared by distilling off, under normal pressure, all the water used for solution and half the water formed in the con-

densation. The residue is mixed with 20 volumes (of the original volume) of methyl or ethyl alcohol, and then half the alcohol distilled off. Subsequently the residue is poured into molds and dried in a chamber through which a current of air is passed. The drying is begun at 60°C. and the temperature is gradually increased to 115-120°C. or higher. A hardened and nonfusible product is formed.<sup>61</sup> One mol of cresol may be condensed with 2 mols of formaldehyde in the presence of triethanolamine, urea and guanidine carbonate. Potassium bromide is added as a dispersing agent. The product is thermally hardened.<sup>62</sup> Cresols are condensed, according to Chestakoff,<sup>63</sup> with formaldehyde in the presence of catalysts of low activity such as oxalic acid, succinic acid, zinc or lead acetate. Material thus obtained is suitable for casting in molds. For this purpose it is mixed with organic monosulphonic acids of high molecular weight readily soluble in the material and is heated for 5-10 hours at 110-130°C. Mathieu<sup>64</sup> uses equal volumes of cresol and 40 per cent formaldehyde solution and condenses the mixture in the presence of acids such as hydrochloric, sulphuric or oxalic, at 65-72°C., until the product solidifies on cooling. The resin is suggested for molding or for mixing with rubber prior to vulcanizing.

Mannesmann<sup>65</sup> obtained a product resembling shellac by condensing cresol and formaldehyde in the presence of halogenated hydrocarbons. The preparation of a resin from hexamethylenetetramine and a rather large proportion of cresol is accomplished by heating a mixture of 1080 lbs. cresol and 140 lbs. hexamethylenetetramine to a temperature of 140°C. After the rapid evolution of ammonia ceases, heating is continued at a temperature of 165°C. for 48 hours, and hot air is blown through the mass to drive off the unreacted cresol. Seventy-eight lbs. of creosote oil (b. p. 220-270°C.) are then mixed into the product at a temperature of 85-125°. Following this, an additional 120 lbs. of hexamethylenetetramine are introduced. The product is a potentially reactive resin, which can be mixed with fillers, pulverized, molded and thermally hardened.<sup>66</sup> From a fraction consisting of a mixture of cresols and xyenols, Mains<sup>67</sup> obtained condensation products with aldehydes, using alkaline catalysts (see also Chapter 24). One hundred and twenty-five parts, for example, of a coal-tar acid containing 75 per cent m- and p-cresols and about 25 per cent xylenols, 96 parts of furfural and 1 part of sodium carbonate are boiled under reflux for 3-4 hours with stirring. The excess water and furfural are distilled off and a dark reddish-brown resin, soluble in acetone, furfural, mixtures of benzene and alcohol and other organic solvents, is obtained. Formaldehyde solution may be used in place of the furfural and by adding small percentages, from 1-10 per cent, of paraform, furfuramide, or hexamethylenetetramine, the resin is converted into a potentially reactive product. Kulas and Pauling<sup>68</sup> heated xylenol with formaldehyde in the presence of an acid catalyst until resin formation had taken place. The hot resin was mixed with more xylenol and formaldehyde and a sufficient quantity of a basic catalyst to leave an excess of alkali in the product. Prolonged heating caused the final hardening of the resin.

A xylenitic resin which has the property of softening but not flowing when placed upon a hot plate, and which sets when subjected to hot-pressing at a tem-

perature of 165°C., has been prepared by Ellis<sup>66</sup> as follows: 30 parts by weight of magnesium oxide are ground with 150 parts of aqueous 40 per cent formaldehyde solution and the mixture is added to 122 parts of xyenols (b. p. 200-225°C.). The batch is agitated at 70°C. for about 25 minutes, at the end of which time the formaldehyde has been entirely consumed. After drying *in vacuo* at 72°C., the light yellow resin, which resembles sulphur in appearance, is mixed in a pebble mill with an equal weight of wood flour. One per cent aluminum palmitate may be added if the resin is to be molded. Drummond and Morgan<sup>70</sup> condensed xylenols distilling between 215-224°C. with formaldehyde in the presence of an acid catalyst. The products are soluble in alcohols, ketones, hydrocarbons and fatty acid esters; they may be used for making air-drying varnishes by heating at 170°C. for 1-2 hours with a drying oil. Synthetic resins are produced by Anderson and MacLaurin<sup>71</sup> through the condensation of formaldehyde with monohydric phenolic substances, boiling between 230-320°C., present in tars obtained by the low temperature distillation of coal. A process of condensing xylenols with formaldehyde to produce resins is given by Landt.<sup>72</sup> The proportions used are, 100 parts of the xyleneol or mixture of xyleneols, 60 parts of 40 per cent formaldehyde solution and

3 parts of ammonia. Reaction is carried on for 3 hours under reflux and the unreacted materials and water are removed by vacuum distillation. This product is suggested for use in varnishes or laminated materials. It may be hardened with hexamethylenetetramine under heat and pressure.

Novotny<sup>73</sup> carries out the condensation of xylenols and aldehydes in such a way that the water is removed substantially as fast as formed, preferably by distillation under atmospheric pressure. This method may be applied to the production of resins from xyleneol and furfural without the use of a catalyst. For example, 32 parts of commercial xyleneol and 21.2 parts of 37-40 per cent formaldehyde solution are placed in a digester equipped with a stirrer and a condenser for distillation. During a period of about 2 hours, 15-18 parts of distillate are collected. The temperature gradually rises during the distillation from 100°C. to about 140°C. at which temperature the product is found to be a hard, grindable resin. By stopping the distillation at a lower temperature soft resins are obtained. The reaction can be performed at a higher temperature (190°C.) if the condenser is equipped with a separator and siphon for returning the xylenols to the reaction mixture and discharging the water.<sup>74</sup> The apparatus in which this is done consists of a vessel in which the condensate separates into layers. The upper layer flows back into the reaction vessel, and the lower layer is drawn off.

Electrolytic oxidation of symmetrical xylenol in acid solution, followed by reduction with sulphur dioxide, yields m-xylohydroquinol and an insoluble resin.<sup>75</sup>

Resinous products proposed for use in the manufacture of varnishes are prepared by treating phenol alkyl ethers, e.g., m-cresol methyl ether, resorcinol diethyl ether or ar-tetrahydronaphthol alkyl ethers, with formaldehyde in the presence of acids. ar-Tetrahydronaphthol alkyl ethers are prepared by sulphonating tetrahydronaphthalene, fusing with alkali and treating the product with alkylating agents.<sup>76</sup> The methyl or ethyl ethers of symmetrical xylenol condense with formaldehyde in the presence of hydrochloric acid to form resins which are soluble in varnish oils (see Chapter 19), and which are also compatible with nitrocellulose.<sup>77</sup>

#### RESORCINOL AND OTHER POLYVALENT PHENOLS

Introducing additional hydroxyl groups in the phenol nucleus causes an increase in the rate of condensation with formaldehyde. The effect is even more marked than the reactivity-increase occasioned by the substitution of alkyl groups. Isolation of resorcinol alcohols as intermediate products in the condensation (see Chapter 14) is extremely difficult, since polymerization is so rapid.<sup>78</sup> At room temperature, resorcinol condenses with formaldehyde sufficiently rapidly that catalysts need not be added. Accordingly, the electrical properties of resorcinol resins are superior to those of resins which may contain traces of harmful constituents added as catalysts. Furthermore, resins from resorcinol or related compounds are characterized by higher tensile strength, less thermoplasticity and lower inflammability than the corresponding phenol-formaldehyde products.

Many years ago Fittig and Remsen prepared a pyrocatechol-formaldehyde resin, but they did not recognize the composition of their material, and mistook it for pure carbon.<sup>79</sup> Labbé<sup>80</sup> has treated pyrocatechol, resorcinol, pyrogallol, quinol and the like with a cold 40 per cent solution of formaldehyde in the presence of an acid to form materials which soon become gelatinous and after some hours are converted into homogeneous, elastic substances. Hard products are obtained by diluting the formaldehyde solution with half its volume of water. These resins are insoluble in water or organic solvents, are unattacked by alkalies and acids and are non-inflammable. The addition of acetone or glycerol to the formaldehyde results in the production of transparent stock. The physical properties of the products may be further modified by incorporating carbohydrates or cellulose. Amber-like substances such as are used in pipe stems have been produced by Peter<sup>81</sup> by heating 10 parts of resorcinol with from 7.5-10 parts of 40 per cent formaldehyde solution. Resins from resorcinol and paraformaldehyde are suitable for uniting layers of fabric or paper. The resin can be formed *in situ* and hardened under heat and pressure.<sup>82</sup> Sound records, made from resorcinol-aldehyde condensation product may be hardened by the use of ferric chloride.<sup>83</sup>

In 1930, wide publicity was given to resinous coatings on paper, used in the manufacture of flexible phonograph records and talking-picture discs. These are

made<sup>85a</sup> by mixing 1000 cc. 40 per cent formaldehyde with 1000 g. resorcinol, and heating the solution slowly until the temperature rises to 70-75°C. The product is kept at this temperature, and stirred until the viscosity is suitable for coating paper. At this point it is rapidly cooled. Two hundred g. of rouge, ground with 600 g. of glycerol, is mixed with the resin, and the product is immediately applied to the paper.<sup>86</sup> Record impressions are embossed upon the coating by means of dies heated to 160°C., and no further hardening operation is required. In making records of this type, Billings and Hurst<sup>87a</sup> employed an emulsion of the resin instead of a solution. This is said to reduce the tendency of the sheets to curl, since the resin does not penetrate the fibers of the paper as much as when a solution is used. Beeswax and borax were employed as emulsifying agents in forming the colloidal dispersion of the resin.

McCoy<sup>88</sup> used pyrogallol and paraform in the presence of gum arabic to produce a red infusible resin. To harden fusible phenol-formaldehyde resins he<sup>89</sup> mixed them with pyrocatechol, tannin and paraformaldehyde (see Chapter 20). Polyvalent phenols are condensed with 40 per cent formaldehyde and sodium, calcium or zinc salts of hydrochloric, salicylic or benzenesulphonic acids are added to prevent shrinkage or development of brittleness.<sup>87</sup> Burmeister<sup>90</sup> prepared fairly rapid-curing compositions by condensing a solid formaldehyde derivative and resorcinol, with the addition of glycerol to control the speed of the condensation.<sup>88a</sup> For the preparation of lacquers which are to be baked after being applied, glycerol may be mixed with polyvalent phenol-formaldehyde resins, after the condensation has taken place.<sup>90</sup>

Resinous condensation products are obtained by Deutsche and Herrmann<sup>90</sup> by heating together polyvalent phenols and acetaldehyde, benzaldehyde or furfural, in the absence of catalysts. For use as a binder for fibrous materials Hawerlander<sup>91</sup> heats a mixture of 1 kg. of resorcinol with 1 l. of 40 per cent formaldehyde solution to 30°C. Three grams of sodium sulphate are then added and the mixture is heated to 75°C. and quickly cooled to 25°C. Sawdust, wood shavings, etc., after being moistened with a volatile liquid (gasoline) are treated with sufficient binding material to cover the surface of the fibrous particles and are then subjected to heat and pressure.<sup>92</sup> Grillet and Cottet<sup>93</sup> condense resorcinol with formaldehyde below 80°C., preferably in the absence of catalysts and in the presence of alcohol, glycerol or sugars. Water is eliminated from the products by distillation *in vacuo* below 50°C. Or the reaction mixture is poured into cold water or salt solution, while it is still viscous. The precipitate thus formed is

washed and air-dried at a low temperature. Ward, Hereward and Ehrhardt<sup>94</sup> modify the process by replacing the resorcinol by a mixture of monovalent and polyvalent phenols. Similarly, Sprenger<sup>95</sup> prepared resins by mixing the condensation products of phenol and formaldehyde with those of resorcinol and formaldehyde, the proportion of resorcinol resin being, in some cases, about 70 per cent of the total. A filling or binding agent (sawdust) may be incorporated. Advantages to be gained by using mixtures of monovalent and polyvalent phenols are noteworthy. For instance, in dry reactions, resorcinol combines with formaldehyde so rapidly that some means must be applied for slowing up the rate. Resorcinol speeds up the phenol-formaldehyde reaction,<sup>96</sup> and reduces the danger of sticking or undercure.<sup>97</sup> Schuhmann and Hahn<sup>98</sup> condense resorcinol with only part of the equivalent amount of an aldehyde and the intermediate product so obtained is converted to an infusible insoluble product by treatment in a separate operation with additional aldehyde. The product can be mixed with fillers, coloring matter and natural or other synthetic resins.

Novotny<sup>99</sup> condenses 1 mol of resorcinol with 0.5 mol or less of paraformaldehyde in the absence of a catalyst at 100-150°C. and then cools the material below 100°C. before the reaction product becomes infusible. Additional paraformaldehyde may then be admixed as hardening agent. The resin may be used in varnishes and coating compositions or in other ways. If the resin is heated, hard but still-fusible resinous material results.<sup>100</sup> Since the condensation of a small amount of resorcinol seems to aid in accomplishing a rapid condensation of phenol with formaldehyde, Novotny<sup>101</sup> makes use of resorcinol to assist the hardening of phenol-formaldehyde resins. For example, to obtain a potentially-reactive soluble product of rapid reactivity 15 parts resorcinol, 45 parts phenol and 31 parts paraformaldehyde are employed. These are heated to 100°C. until the mixture is clear and the desired viscosity has been obtained. Alcohol may be added to stop the reaction, or if a solid dry resin is desired the material can be placed in pans and rapidly cooled. Moss<sup>102</sup> condenses resorcinol or its isomers with acetone (see also Chapter 25), in the presence, preferably, of concentrated hydrochloric, sulphuric or phosphoric acid. A yellow oil, which gradually is converted into a yellow-pink solid, is the product. The reaction requires 24 hours at room temperature or 1 hour at 60-70°C. The resin is said to be compatible with cellulose acetate, both in solution and in plastic compositions.

Besides the polyvalent phenols which have been discussed above, many other phenolic bodies have been used in the preparation of resins. Some of these yield oil-soluble compositions, and will be described in Chapter 19.

Adhesive compositions for reinforced glass may contain cellulose acetate and a resin (e.g., from hydroxybenzyl alcohol), modified by glycerol.<sup>103</sup> The dihydroxybenzophenones condense with aldehydes in the presence of acid catalysts (including zinc and aluminum chlorides), and the resins thus obtained are suggested for

use with cellulose esters<sup>104</sup> in the preparation of a transparent adhesive employed in the manufacture of laminated glass. A number of modifiers are included in the adhesive product, which may contain simultaneously the following: cellulose nitrate, camphor, dibutyl phthalate, synthetic resin, benzene, alcohol, butyl alcohol, butyl acetate and ethyl acetate. Dihydroxybenzophenone is prepared<sup>105</sup> by condensing phenol with carbon dioxide at 70 atmospheres and 105-110°. Corresponding compounds are obtained from the cresols, but resorcinol and  $\beta$ -naphthol are too reactive, and resinification occurs before the substituted benzophenone can be isolated. At higher pressures phenol reacts with carbon dioxide to yield salicylic acid.

#### SALICYLIC ACID AND OTHER PHENOLIC SUBSTANCES

By condensing aromatic hydroxycarboxylic acids with aldehydes a series of resins soluble in mild alkalis has been obtained<sup>106</sup> (see also Chapter 20). Salicylic acid, for example, may be heated with 30 per cent aqueous formaldehyde for 20 hours to give a white precipitate. This is separated, freed from excess water and further heated until a sample sets to a clear glass-like substance. The duration of treatment may be shortened by the addition of hydrochloric acid. The hard resin obtained is soluble in alcohol, acetone or weak alkalis. It is suggested for leather finishing and for treating felts in the manufacture of hats. Similar resins are obtained from hexamethylenetetramine and mixtures of *o*- and *p*-hydroxybenzoic acids, from 1,3,4-hydroxytoluic acid and paraformaldehyde in the presence of ammonium acetate and from salicylic acid and benzaldehyde in the presence of ammonia. These products are yellow to yellowish red in color, and are soluble in weak alkalis. Two mols of salicylic acid may be condensed with 1 mol of formaldehyde to give a dihydroxydiphenylmethane dicarboxylic acid. The latter product is then caused to react with a monobasic acid such as rosin or tung oil acid and glycerol to yield a product to be incorporated in cellulose ester lacquers.<sup>107</sup>

Conditions necessary for the preparation of resins from various aromatic acids are as follows: *m*-hydroxytoluic acid with formaldehyde in alkaline solution at 30°C.; *o*-methoxybenzoic acid, formaldehyde and concentrated sulphuric acid at 100°C.; *o*-ethoxybenzoic acid and formaldehyde at 140-150°C. under pressure; 2-ethoxynaphthalene-3-carboxylic acid at 100°C. with paraformaldehyde in the presence of acetic and concentrated hydrochloric acids; a mixture of *o*-, *m*- and *p*-hydroxytoluic (cresotinic) acids with acetaldehyde at 130-140°C. under pressure in the presence of zinc chloride.<sup>108</sup> Esters of these aromatic hydroxycarboxylic acids may be used<sup>109</sup> to produce resins which are almost insoluble in alcohol, benzene or dilute alkali, but soluble in ether, amyl acetate or ethyl acetate. They can be used to prepare lacquers which are unaffected by light. Concentrated sulphuric acid, concentrated hydrochloric acid, zinc chloride or glacial acetic acid are used to catalyze the condensation of ethyl or phenyl salicylate with formaldehyde at 100°C. The methyl ester of hydroxytoluic acid (cresotinic acid) reacts with paraformaldehyde at 100°C. in the presence of zinc chloride and glacial acetic acid, and the ethyl ester of *p*-hydroxybenzoic acid combines with methylal when these sub-

stances are heated together under pressure at 120°C. Pink<sup>110</sup> prepared a reaction product of salicylic acid with a molecular proportion of hexamethylenetetramine in alcoholic solution. The solvent is removed and a viscous syrup is formed which gives a reddish precipitate with ferric chloride. A resin intended for dental use is made by Andresen<sup>111</sup> by condensing eugenol with formaldehyde. The reacting materials may be mixed with burnt alum, and the pasty condensation product mixed with zinc oxide.

The hydroxybenzoic acids have a tendency to form resins as a result of oxidation, reduction and dehydration reactions. Von den Velden<sup>112</sup> observed that the reduction of 2- and 4-hydroxybenzoic acids with sodium amalgam in acid solution yielded resinous matter, and Perkin,<sup>113</sup> oxidizing 3-hydroxybenzoic acid with potassium persulphate in an aqueous sulphuric acid solution at 30°C. for 12 hours, obtained some colored resinous bodies. Salicylic acid upon dehydration gives complex anhydride substances that do not melt when heated though by treatment with alkali may be hydrolyzed back to the parent substance. Phosgene acting on a pyridine solution of salicylic acid gave disalicylic acid anhydride and amorphous dehydration products.<sup>114</sup> A complex mercury anhydride  $-(C_7H_3O_2Hg)_n-$  was obtained by heating at 100°C. an aqueous solution of salicylic acid with mercuric oxide.<sup>115</sup>

Aryloxyaliphatic acids are heated with formaldehyde or a substance which yields formaldehyde to produce hard resins which are almost colorless and transparent, easily soluble in alcohol, acetone and other organic solvents and in mild alkalies.<sup>116</sup> For example, phenoxyacetic acid when boiled under reflux with 40 per cent formaldehyde solution in the presence of hydrochloric acid yields a colorless oil lighter than water. This oil, when washed several times with water, can then be heated in an open vessel at 120-130°C. until a test portion solidifies on cooling. Products of analogous properties can be obtained from cresoxyacetic acid, xylyloxyacetic acid,  $\alpha$ - or  $\beta$ -naphthoxyacetic acid, or from the corresponding propionic and butyric acids. Pyrocatecholmonoacetic acid also gives a similar product when treated with formaldehyde. The use of a quantity of aldehyde less than equivalent to the aryloxyaliphatic acid renders the process more easily controllable. At increased pressures and temperatures the condensation proceeds much more rapidly and the use of catalysts may be omitted. Binding agents for anti-halation materials for use on photographic plates are alkali-soluble resins derived from salicylic acid and paraldehyde, from phenoxyacetic acid and formaldehyde or from o-methoxybenzoic acid and formaldehyde.<sup>117</sup> Aliphatic or aromatic aldehyde- or keto-carboxylic acids, which contain the carboxyl group either in the nucleus or in the side chain, can be condensed with phenols or naphthols by the use of catalysts, such as hydrogen chloride.<sup>118</sup> For example, m-aldehyde-phenoxyacetic acid is melted with phenol and treated at 40-50°C. with concentrated hydrochloric acid to obtain a hard resin. By the action of chloroacetic acid on 2-aldehyde-4-methyl-phenol the compound 2-aldehyde-4-methyl-phenoxyacetic acid is obtained, which, condensed with  $\alpha$ -naphthol, also yields a resin.

Benzophenone-2,4-dicarboxylic acid can be condensed with m-cresol. The

resin from glyoxylic acid and phenol has an especially bright yellow color in caustic soda solution.

o-Benzoylbenzoic acid condenses<sup>119</sup> with phenols (xlenols, cresols, naphthols) in the presence of concentrated sulphuric acid to form amber-like brittle resins. The temperature is kept lower than that at which esterification or anthraquinone formation takes place. Resins made in this way readily undergo further condensation with formaldehyde, furfural or acetaldehyde, especially in the presence of ammonia, to yield fusible soluble products which, when mixed with cellulose esters, are capable of forming transparent films. Typical keto-aromatic acids which may replace o-benzoylbenzoic are  $\alpha$ -hydroxy-o-naphthoylbenzoic or 2',5'-dichloro-2-benzoylbenzoic acids. Resinous products are obtained<sup>120</sup> either by (1) treating mixtures of phenols and aromatic carboxylic acids with aldehydes, or substances capable of yielding aldehydes, preferably in the presence of alkalis, or by (2) reacting phenols and carboxylic acids separately with aldehydes, and subsequently causing the products to interact, or, by (3) treating mixtures of phenol-aldehyde condensation products and carboxylic acids, or of carboxylic acid-aldehyde condensation products and phenol with aldehydes. Whichever method is adopted, the products are separated from solution, and heated to temperatures above 100°C. to obtain resins soluble in dilute alkalis.

Glycol-monoaryl ethers can be heated with formaldehyde in the presence of an acid to produce resin-like substances<sup>121</sup>. Thus, for example, ethyleneglycol-monophenyl ether,  $C_6H_5-O-CH_2-CH_2OH$ , is heated with formaldehyde in the presence of 3.5 per cent hydrochloric acid, with the addition of phenols. The ethers of the phenols may be used in place of the phenols. From formaldehyde and glycol-monophenyl ether and the hydroxyethyl ethers of the cresols or the naphthols, viscous, almost colorless oils, insoluble in alkali, soluble in acetone, benzene, amyl acetate and cyclohexanone are first obtained and are of use in the rubber industry. On long standing or on heating to above 80°C. they form extremely elastic, gummy substances, which can be kneaded. They do not melt, and are insoluble in all the usual solvents. They can be used to increase the elasticity of other synthetic resins by combining their preparation with that of the synthetic resin involved and giving the mixture a final heating to cause the intermediate glycol compound to assume the plastic form. Formaldehyde may be condensed in large excess with a phenol having a long saturated hydrocarbon side-chain such as thymol, p-ter-butylphenol, o- and p-cyclohexylphenol,

<sup>119</sup> H. A. Bruson, U. S. P. 1,934,032, Nov. 7, 1933, to Resinous Products & Chemical Co.; *Chem. Abs.*, 1934, 28, 663.

o-phenylphenol and  $\beta$ ,  $\beta'$ -bis(4-hydroxy-3-methylphenyl) propane. The condensation takes place in contact with an energetic base.<sup>122</sup>

Harvey<sup>123</sup> condenses cashew-shell oil (a phenolic material) with aldehydes, in the presence or absence of catalysts, to produce synthetic resins that may be subsequently hardened. For details, see Chapter 61. Aryl esters of aliphatic acids are condensed by Seebach with compounds containing active methylene groups, to obtain resinous products.<sup>124</sup> Thus, hexamethylenetetramine is condensed with diphenylcarbonate,  $(C_6H_5)_2CO_2$ , to give a solid product. The reaction can be performed by simply pressing the two powdered substances together, with the application of heat. The product is said to be fully hardened within a few minutes. In fact, careful control of the relative amounts of reactants is necessary, lest the reaction become too violent.

A resinous composition for molding is prepared by Ellis<sup>125</sup> from cyclohexanol and formaldehyde. Ten parts of cyclohexanol, for example, are heated with 3 parts of paraformaldehyde and 5 parts of 50 per cent aqueous potassium hydroxide solution for 3 hours. The resinous material is dissolved in benzene and, on evaporating, a dark-brown clear transparent fusible resin is obtained. To this can be added 5-10 per cent of hexamethylenetetramine, and fillers, and the product can be molded under heat and pressure or it can be molded cold and baked carefully to bring about the hardening reaction. Moss<sup>126</sup> prepared resins compatible with cellulose acetate from a diphenylnaphthene and formaldehyde. For example, 264 parts of diphenylol cyclohexane, resulting from the condensation of phenol with cyclohexanone,<sup>127</sup> 75 parts of 40 per cent formaldehyde solution and 66 parts of phosphoric acid are heated under reflux until a resin is obtained which solidifies at about 50°C. It is purified by washing with water. Fusible resins can be treated for the removal of free phenol or formaldehyde by reaction with cyclohexanone.<sup>128</sup> Condensation products made by interaction of a phenol ( $\beta$ -naphthol, 4,4'-dihydroxy- $\beta$ , $\beta'$ -diphenylpropane) with formaldehyde and an alkyl- or cycloalkyl-amine (piperidine, piperazine) have been proposed as anti-agers for rubber.<sup>129</sup>

The condensation of diarylacetals with formaldehyde to yield resins has also been accomplished.<sup>130</sup> When 2 mols of acetal are condensed with 1 mol or less of formaldehyde, viscous oils or soft resins which liquefy without decomposition at high temperatures and are soluble in organic solvents are produced. Larger proportions of formaldehyde give viscous, insoluble, less fusible resins.

Dreyfus and Schneider<sup>131</sup> have utilized the thiophenols (see Chapter 59) in place of phenols for preparing resins which can be incorporated in lacquers containing cellulose esters. Such compounds as the thiocresols,<sup>132</sup> thioxylanols, benzyl mercaptan or di-thiophenylol propane condense with formaldehyde or acetaldehyde. Acid or alkaline catalysts may be used, but are not necessary. The resin and cellulose derivative are dissolved in a mutual solvent, and plasticizers

<sup>132</sup> Aldehydes condense more rapidly with thiocresols than with cresols. G. L. Stadnikov, N. M. Gavrilov and V. E. Rakovskii, *J. Chem. Ind. (Moscow)*, 1925, 2, 315.

(triacetin, diethyl tartrate, dibutyl tartrate) are added. It is also possible to prepare a sulphur-containing resin of the phenol-aldehyde type by condensing thioformaldehyde or thioacetaldehyde with phenol. Still another alternative is to condense phenol and formaldehyde in the presence of ammonium sulphide. The reaction requires 6 hours at 180°C. under increased pressure.<sup>133</sup> Other sulphur resins are discussed in Chapter 59.

### CHLORINATED PHENOLS

Resins made by condensing chlorinated phenol<sup>134</sup> with formaldehyde<sup>135</sup> are characterized by being chemically inert and practically non-inflammable. Aylsworth (see also Chapter 20) prepared chlorinated phenol-aldehyde resins,<sup>136</sup> and used them for incorporation with phenol-formaldehyde products. Steinmetz<sup>137</sup> specified the following procedure: about 136 parts of monochlorophenol are mixed with 75-100 parts of 40 per cent formaldehyde solution, and the mixture is heated under reflux with 5-10 per cent hexamethylenetetramine. A soluble fusible resin is formed, which can be hardened by the addition of sufficient quantities of hexamethylenetetramine.

Brunner<sup>138</sup> treats an aqueous solution of formaldehyde and phenol at 40-45°C. with concentrated hydrochloric acid to obtain a viscous resin, or at 5-10°C. to obtain 6,8-bischloromethylbenz-1,3-dioxan, melting at 117°C. p-Cresol at 20°C. gives 3,5-bischloromethyl-p-cresol, melting at 86°C. while technical cresols at 40°C. give a resin. Faster reactions at higher temperatures give resinous products. The products can be further condensed with phenols, hydrogen chloride being eliminated. The crystalline compounds are intermediates for the preparation of dyestuffs, synthetic resins and tanning materials.

A mixture of benzoyl cyanide and resorcinol dissolved in dry ether containing a small quantity of zinc chloride, saturated in the cold with hydrogen chloride, quickly deposits a reddish-brown resin.<sup>139</sup>

Datta and Prosad<sup>140</sup> dissolved the three isomeric hydroxybenzoic acids in aqueous ammonia and treated with iodine. The expected iodo-acid was crystallized from acetic acid but complex pink-colored material was also obtained insoluble in boiling solvents. p-Hydroxybenzoic acid gave a complex anhydride when heated with phosphorus oxychloride in ether solution.<sup>141</sup> This has been extended to cover mixtures of hydroxybenzoic acids or their homologues by treatment with acetyl chloride or acetic anhydride, to form resins soluble in acetone, aromatic hydrocarbons and linseed oil. Such solutions applied to wood yield hard glossy films

<sup>133</sup> G. Brunn, Austrian P. 100,564, 1921; *Brit. Chem. Abs.* B, 1926, 890.

<sup>134</sup> Chlorinated toluene reacts with phenol to produce resins. These are described in Chapter 56.

<sup>135</sup> A large number of crystalline substances of the general formula  $\text{HOR}_1\text{CHXR}_2\text{OH}$ , where  $\text{R}_1$  and  $\text{R}_2$  are halogenated benzene residues, and X is hydrogen or an alkyl or aryl group, have been prepared by reacting halogenated phenols with formaldehyde. Such compounds are useful as moth-repellants. M. Weiler, B. Wenk and H. Stötter, U. S. P. 1,707,181, March 26, 1929; *Chem. Abs.*, 1929, 23, 2257. M. Weiler, B. Wenk and H. ## Chapter 18

### Phenol-Aldehyde Resins

#### VI. Employment of Other Aldehydes

In the manufacture of phenol-aldehyde resins other aldehydes may be used in place of formaldehyde and its polymers. For instance, acetaldehyde, butyraldehyde, benzaldehyde, furfural,<sup>1</sup> carbohydrates<sup>2</sup> (such as sucrose), glycerol (which is readily dehydrated to acrolein), aldehyde derivatives (methylals) and some unsaturated hydrocarbons, e.g., acetylene (which in many of its reactions behaves as if it were the anhydride of acetaldehyde<sup>3</sup>) have been suggested. In addition, ketones, for example, acetone, may be condensed with phenols to yield either resins or compounds which give resinous bodies on treatment with aldehydes. A discussion of the latter types of substances is also included in this chapter. The employment of all these materials in place of formaldehyde is of course contingent on some advantage to be gained thereby, such as a cheaper product, or one with more desirable characteristics.

##### ACETALDEHYDE

Phenol combines with acetaldehyde to form crystalline derivatives, though the reactions may be directed in such a manner that the major portion of the yield is resinous.<sup>4</sup> In general, synthesis of soluble fusible materials is effected and there is little danger of an infusible product being formed. In order to obtain infusible masses, such as are desired in the manufacture of cast articles, moldings and varnishes, more active methylene-containing agents are generally used, e.g., formaldehyde, paraformaldehyde and hexamethylenetetramine.

A water-soluble resin can be prepared by adding 44 parts of acetaldehyde to a cooled solution of 216 parts of crude cresol in 100 parts of sulphuric acid (sp.gr. 1.83) and 1000 parts of alcohol and heating under reflux.<sup>5</sup> Afterwards the alcohol is distilled off with steam and the residue poured into cold water, from which crude dihydroxyditolylethane separates as a hard resin. This is broken up and added to 500 parts of sodium sulphite dissolved in water and 200 parts of 30 per cent formaldehyde are added. The mixture is warmed to dissolve the material and is then heated for 5-6 hours at 95-100°C. The solution is neutralized, filtered to free from precipitated impurities, and evaporated to dryness.<sup>6</sup>

In another procedure phenol is condensed with acetaldehyde, paraldehyde, metaldehyde or tetraldehyde, in the presence of acids, bases, neutral, basic or acid

<sup>1</sup> See Chapter 24 for phenol-furfural resins.

<sup>2</sup> See Chapter 36 for phenol-carbohydrate resins.

<sup>3</sup> J. A. Nieuwland and S. A. Flood, *J.A.C.S.*, 1928, 50, 2566. W. Heckel and P. Nashan (U. S. P. 1,943,385, Jan. 16, 1934, to Gutehoffnungshütte Oberhausen A.-G.; *Chem. Abs.*, 1934, 28, 2018) have suggested a catalytic treatment of acetylene as a means of procuring acetaldehyde.

<sup>4</sup> Mention has already been made (Chapters 13 and 16) of the observations of A. Baeyer, *Ber.*, 1872, 5, 1095; A. Claus and E. Tramer, *Ber.*, 1886, 19, 3004; J. Abel, *Ber.*, 1892, 25, 3477 and A. Smith, U. S. P. 643,012, Feb. 6, 1900 on the reaction of acetaldehyde with phenol.

<sup>5</sup> Swiss P. 71,652, 1916, to Badische Anilin- & Soda Fabrik.

<sup>6</sup> Sulphite waste-liquor has been suggested as a source of acetaldehyde. See O. W. Knight, U. S. P. 1,143,714, June 22, 1915. See Chapter 36.

salts, to obtain a fusible resin. The latter is soluble in benzene and alcohol and can be further treated with formaldehyde to give an insoluble infusible resin.<sup>7</sup> For instance, 100 g. of phenol or cresol<sup>8</sup> are used with 2 cc. of concentrated hydrochloric acid and 46 g. of acetaldehyde. Kendall<sup>9</sup> obtained a fusible resin capable of being hardened with an active methylene-producing agent, by reacting 100 parts of phenol with 25 parts of acetaldehyde and approximately 2 parts of hydrochloric acid or a small proportion of sulphuric acid.

Steindorff and Balle<sup>10</sup> suggested that reaction between acetaldehyde and phenols (or cresols) be carried out in solvents such as carbon tetrachloride or trichloroethylene. Condensing agents, e.g., hydrochloric acid, sulphuric acid and thionyl chloride, were employed. The products were yellow resins soluble in the usual organic solvents, in linseed oil and in solutions of caustic alkali, and insoluble in aqueous alkali bicarbonate. As an example, technically distilled cresol is dissolved in an equal weight of carbon tetrachloride, concentrated hydrochloric acid is added and the mixture stirred with paraldehyde at 25-30°C. for 16 hours. It is then neutralized and steam-distilled to recover the solvent and any unreacted cresol and the resin is thoroughly washed with warm water.

A condensation product from acetaldehyde and phenol or cresol was employed by Novotny<sup>11</sup> for impregnating fibrous blanks which are to be used for making such articles as phonograph records, panels and gears. One hundred parts of phenol and 75 parts of acetaldehyde are brought into reaction by means of a catalyst (hydrochloric or sulphuric acid). The acid is removed by blowing with steam or by neutralizing with ammonia. The resin so prepared does not harden readily on heating but retains its thermoplastic properties for a long period. Protracted baking in an oven will, however, bring about hardening to an infusible form. Hence it may be cold molded. The addition of 2 per cent of nigrosine black or zinc chloride as a final catalyst assists in the hardening. An intermediate product may be made from 100 parts of phenol and 35 parts of acetaldehyde in the presence of an acid and adding an acetaldehyde compound of sodium bisulphite as a hardening agent. Impregnation of paper, cardboard or other supports is effected by using a solution of the condensation product in a mixture of benzol and alcohol. A 5 per cent solution was recommended by Novotny.

A resinous substance which remains soluble and fusible on heating was obtained by Potter and Fleet<sup>12</sup> by condensing phenol or its homologues with acetaldehyde or its polymers. The proportions used were 100 parts by volume of phenol, 75 parts of paraldehyde and 5 parts of concentrated sulphuric acid. Similarly 100 parts of phenol, 45 parts of paraldehyde, 45 parts of 40 per cent formaldehyde and 5 parts of ammonium hydroxide (sp.gr. 0.88) may be used. More formaldehyde (or one of its polymers) can be added at some stage of the process to reduce the solubility and fusibility of the resulting material.

A readily fusible resin was made from phenol and acetaldehyde by Ellis,<sup>13</sup> employing an excess of phenol, and an acid catalyst, e.g., sulphuric acid. The product, after hardening treatment with furfural (aided by a mild alkaline catalyst such as sodium carbonate), can be incorporated with hexamethylenetetramine<sup>14</sup> and the resulting mixture used for molding. Clear, readily soluble substances

result from the action of gaseous aldehydes (diluted with inert gases, e.g., nitrogen or carbon dioxide) upon phenols or solutions containing them.<sup>15</sup> For example, a mixture of acetaldehyde vapor and carbon dioxide is passed at 50°C. for about 5 hours through phenol containing a little dilute hydrochloric acid.

Paraldehyde may be substituted for acetaldehyde. Thus, Ellis<sup>16</sup> obtained a hard brittle resin by slowly adding 4 lb. of paraldehyde to 8 lb. of phenol, containing 1 fluid ounce of concentrated hydrochloric acid. The mixture became hot and was allowed to stand over night, after which it was heated to 150°C. under reflux for 1 hour. The resulting resin, with 10 per cent of hexamethylenetetramine, dissolved in an equal weight of denatured alcohol, was incorporated with the same weight of wood flour. The mix was dried in a vacuum oven. In the molding press, discs of the dried material cured readily in 2 minutes at 160°C. and 1000 lb. pressure. Aluminum palmitate or some other water-insoluble soap, blended with the resin in powder form, was effective in preventing sticking during molding.

A soluble fusible condensation product was made by Baekeland and Gotthelf<sup>17</sup> by heating 1000 g. of phenol with 550 g. of paraldehyde and 50 cc of concentrated hydrochloric acid. The water separated into a distinct layer and was removed. Addition of an agent with an active methylene group transformed the resin into a material capable of further hardening. Crystalline dihydroxydiphenylethane, prepared from acetaldehyde and phenol, may be converted into a potentially reactive, brittle, transparent resin. Baekeland<sup>18</sup> heated, for example, 100 parts of dihydroxydiphenylethane with 10 parts of paraform or 12 parts of hexamethylenetetramine first at about 180°C. and later at 200°C. until a resin which solidified on cooling was obtained.

Matheson<sup>19a</sup> effected the reaction of phenol and acetaldehyde at 50-80°C. under pressure in the presence of less than 1 per cent of a condensing agent comprising a halogen derivative of a non-metal, as phosphorus oxychloride, acetyl chloride, benzyl chloride or the chlorides of sulphur.

#### BUTYRALDEHYDE

A resin was prepared by Ellis<sup>19</sup> by heating phenol and butyraldehyde with concentrated hydrochloric acid. A soft viscous brown substance was formed, which hardened considerably on heating. Furfural, with potassium carbonate as a catalyst, as well as hexamethylenetetramine, served to harden the product, which was adaptable for hot and cold molding or for varnishes, adhesives and impregnants. A related procedure is described by Schrimpe.<sup>20</sup>

#### BENZALDEHYDE

Gluud and Breuer<sup>21</sup> obtained fusible dark brown resins soluble in alcohol, benzene and aqueous solutions of alkali by condensing benzaldehyde with phenol

<sup>21</sup> W. Gluud and P. K. Breuer, *Ges. Abhandl. Kennt. Kohle*, 1919, 4, 221; *Chem. Abs.*, 1921, 15, 3550.

or cresols. Fifty parts of phenol, 53 parts of benzaldehyde and 2 parts of ammonium chloride were heated for 7 hours on an oil bath at 120°C. Coatings obtained from a spirit varnish made with this resin were somewhat soft. Michael<sup>22</sup> also studied the formation of resinous bodies from benzaldehyde and phenols.

In a process used by Novotny and Romieux<sup>23</sup> the reaction of phenol with benzaldehyde is carried out in such a manner that the water liberated during condensation is removed almost immediately after it is formed. The product was hardened by heating with small quantities of inorganic acids, acid salts or methylene-engendering bodies.

According to Driver,<sup>24</sup> o- and p-hydroxybenzaldehyde do not react with phenol in the presence of sodium or potassium hydroxide, but on refluxing with concentrated hydrochloric acid, resins are secured in good yields.

From a study of the derivatives of p-nitrobenzaldehyde, King and Lowy<sup>25</sup> concluded that this substance may be condensed with two molecular equivalents of phenol, resorcinol, thymol, o-nitrophenol or o-methylanisole to yield amorphous solids

An essential oil having an aldehyde base, e.g., oil of cassia, oil of cinnamon or vanillin, was treated with a phenolic compound by McIntosh<sup>26</sup> to give a fusible, soluble resin which by further heating could be transformed into a hard, infusible product. One hundred grams of oil of cassia, for example, were digested under reflux for about 2 hours with 200 g of phenol and 2-5 g. of sulphuric or hydrochloric acid. The material obtained was shiny, hard, black, and sweet-smelling and was reported to be suitable as a varnish or shellac substitute.

A resin, stated to give water-resistant, elastic films, has been formed by the condensation of phenols with the oxidation products of certain hydrocarbons.<sup>27</sup> Saturated or unsaturated hydrocarbons with a chain of 2-6 carbon atoms (such as ethylene and other gaseous products from the cracking of oils) are oxidized by heating at 400-700°C. in the vapor phase (using acid phosphates as catalysts) with 5-10 per cent of oxygen. The resulting yellow oil, containing various aldehydes, principally formaldehyde, and some aliphatic acids, alcohols and esters, is reacted with a phenol at 95-100°C. for 2-3 hours. After separating any water present, further heating under vacuum at the same temperature for 2 hours yields a resin which is fusible, but which can be hardened to an infusible bubble-free mass by an additional 12-hour heating.

#### ACETYLENE

Wenzke and Nieuwland<sup>28</sup> studied the catalytic condensation of acetylene with phenol, the cresols, the naphthols, resorcinol and hydroquinone, pyrogallol and phloroglucinol, and various substituted phenols. Resorcinol and acetylene yielded ethylidene dioresorcinol with linkage ortho and para, respectively, to the two hydroxyl groups. This compound then lost a molecule of water to form dihydroxymethylxanthene. The catalysts used consisted of mercury salts in concentrated sulphuric acid. It was stated that phenol absorbed acetylene very readily, but the product formed did not have the properties of the ethylidene diphenol (dihydroxydiphenylethane) prepared from acetaldehyde and phenol by the method

<sup>28</sup> H. H. Wenzke and J. A. Nieuwland, *J.A.C.S.*, 1924, 46, 177.

of Claus and Trainer.<sup>20</sup> This seemed especially striking since the same catalysts (mercury salts) can be employed to convert acetylene to acetaldehyde.<sup>20</sup> In a later work, Nieuwland and Flood<sup>21</sup> reported that acetylene and acetaldehyde are probably alike in their reaction with phenols. The primary reaction product of the catalytic condensation of acetylene and resorcinol, as well as of acetaldehyde and resorcinol, was identified as vinyl resorcinol.<sup>22</sup>

Matheson and Nieuwland<sup>23</sup> passed dry acetylene into phenol or cresol containing 2.1-4.0 per cent of mercurous sulphate and 1-2 per cent of sulphuric acid at 90-115°C. until approximately 14 per cent of acetylene was absorbed. Glacial acetic acid served as a solvent and the temperature was raised to 120-150°C. at the end of the operation. The product may be combined with aldehydic hardening agents and rendered infusible

Fig. 66.  
Reinforced Haveg Apparatus.

Courtesy Haveg Corporation

and insoluble by heating under pressure. The use of other hydrocarbons containing a triple bond was suggested. Matheson and Skirrow<sup>24</sup> described a process of treating a soluble fusible acetylene-phenol compound with aldehydes and other hardening agents to transform it to the infusible insoluble stage. Thus, an acetylene-phenol resin is treated with less than 35 per cent of acetaldehyde and then hexamethylenetetramine is added. When over 35 per cent of acetaldehyde is employed, generally no additional agent is necessary. The product can be used in molding materials or as a varnish.<sup>25</sup>

According to Melamid,<sup>26</sup> if acetylene is admitted for a considerable period of time into a mixture of cresols (in the presence of sulphuric acid and a mercury salt as catalyst) and the latter then is submitted to a vacuum distillation, a high-boiling distillate is obtained, which is completely soluble in water when sul-

phonated. This exhibited the properties of a tanning agent. The distillation residue is a hard, transparent resin soluble in alcohol and benzene.

Melamid gives the following procedure: Two hundred parts by weight of commercial cresol are added with cooling to about 40 parts of 50 per cent sulphuric acid, 5 parts of mercuric sulphate and 1 part of ferric chloride. A slow current of acetylene is admitted with stirring for a period of about 12 hours at room temperature. The resulting viscous mass is dissolved in benzene, separated from the catalyst by filtration and washing with water, dried and submitted to fractional distillation under a pressure of 8 mm. Up to 100°C. benzene and cresols pass over together, and between 100-200° a liquid product is obtained, leaving behind the resin described above.

In an analogous procedure<sup>37</sup> crude phenol or cresol is added to a solution of mercuric oxide in 30 per cent sulphuric acid and acetylene is passed into the vigorously stirred mixture. When the absorption is complete, the viscous reaction product is separated from the aqueous solution and washed. Excess phenol is driven off by steam and the mercury is eliminated by treatment with alcohol or benzene. A transparent residue, melting at about 100°C., was found to be soluble in sodium hydroxide but not in sodium carbonate. If phenolsulphonic acid is used instead of phenol, the condensation product is soluble in water and is said to be useful as a tanning material.

A permanently fusible acetylene-phenol-aldehyde resin is described by Novotny and Kendall.<sup>38</sup> This is made by heating a phenol-acetylene resin with 0.5 per cent of sulphuric acid in an autoclave to a temperature of about 125°C. and gradually adding up to about 8 per cent of paraldehyde with further increase of temperature and pressure. The acid is then neutralized and the resinous bodies removed. The material was stated to resemble shellac in its properties. A better grade of resin was secured by treatment with steam. Infusible products were obtained by heating the resin with hexamethylenetetramine at 90-200°C.

Methods of preparing soluble fusible acetylene-phenol compounds have been discussed by Schrimpe.<sup>39</sup> He treated 2.2 kg. of phenol, 880 cc. of water, 220 g. of concentrated sulphuric acid, and 45 g. of mercuric sulphate with acetylene. Additional mercuric sulphate tends to further activate the reaction. Schrimpe stated that the resin is of the type prepared by Baekeland and Gotthelf<sup>40</sup> from phenol and acetaldehyde, and that the first reaction product is probably vinyl sulphuric acid,  $\text{CH}_2=\text{CHSO}_3\text{H}$ , which reacts with phenol to form ethylidene diphenol (dihydroxydiphenylethane).

A modified catalyst consists of a porous substance, e.g., kieselguhr or wood charcoal, impregnated with a solution of mercuric oxide in sulphuric acid. This mass is introduced into a solution of phenol in benzene and the mixture is treated with acetylene.<sup>41</sup>

The material obtained by condensing phenols with acetylene under pressure at 100-300°C. in the presence of an organic base, instead of treatment with aldehydes, may be sulphonated to yield tanning agents, esterified with polybasic organic acids, or condensed with ethylene oxide to give water-soluble ethers.<sup>42</sup>

In place of mercury salts, the use of zinc or cadmium salts of acetic or other organic acids has been suggested.<sup>43</sup> No sulphuric acid is needed with this type of catalyst, the acetylene being introduced into phenol, cresol, o-chlorophenol, resorcinol and similar substances at 100-300°C. Reaction is usually carried out at 5-10 at-

mospheres pressure under nitrogen. With phenol a clear resin (m.p. 100-130°C) was obtained, which could be hardened by hexamethylenetetramine or esterified with linoleic acid to form a soft, alkali-soluble resin. Darker resins resulted when resorcinol, diphenylpropane and o-chlorophenol were used.

#### ACETONE AND OTHER KETONES

Condensation products of phenol and acetaldehyde, as previously mentioned, have a tendency to be crystalline. Compounds made by the interaction of acetone and phenol exhibit this tendency to a still greater degree. Usually 4,4'-dihydroxydiphenyldimethylmethane is formed first, this is separated and purified, and then reacted with additional acetone. Or a more reactive aldehyde (as formaldehyde) is used to give resinous products.

Dianin<sup>44</sup> prepared 4,4'-dihydroxydiphenyldimethylmethane (p-diphenyldimethylmethane) by heating 220 g. of acetone with 1600 g. of phenol, 1800 cc. glacial acetic acid and 600 cc. hydrochloric acid (sp.gr. 1.19) at 40-50°C. for several days in a bomb. The compound

crystallized as needles or prisms, having a melting point of 151-152° and could be recrystallized from water. Arvin<sup>45</sup> states that by using an acid-soluble boron compound such as boric acid in conjunction with an acid condensing agent such as hydrochloric, or sulphuric acid, the yields of p-phenyldimethylmethane are increased and purer products result.

Jordan<sup>46</sup> condensed m- and p-cresol with acetone, using hydrochloric acid, phosphorus oxychloride or metallic halides at temperatures up to 100°C, and obtained dimer products, useful as disinfectants and deodorants. The material derived from m-cresol was considered to have the formula

and that from p-cresol was thought to be

When a mixture of m- and p-cresols was used, the products were separated by fractional crystallization from ether, the m-cresol derivative crystallizing while the p-cresol form remained in the mother liquor. The former melts at 73-75°C. and boils at 187°C., the latter boils at 192° (0.8 mm. mercury). Condensations were made also with methyl ethyl ketone and cyclohexanone and resulted in compounds of related structure. The vacuum-distilled products solidified on cooling to clear or light-yellow amorphous masses.

Niederl and Casty<sup>47</sup> conducted an extensive study of the structure of acetone-cresol compounds, and proposed a number of formulas. They stated that if a mixture of o-cresol and acetone or phorone is treated with cold concentrated sulphuric acid there results a condensation product which may be termed di-o-tolylol-phorone (m.p. 245°C.). This gives sodium and potassium salts when treated with alcoholic alkali hydroxide solution. Similarly p-cresol and acetone furnishes di-p-tolylolphorone ether (m.p. 137°). The constitution of di-m-tolylolphorone ether follows from the production of thymol, menthol and trimethylcoumarone from it, by successive oxidation, elimination of carbon dioxide or water, and hydrogenation.

Gsell<sup>48</sup> reported producing solid substances by boiling 50 cc. of acetone and 50 g. of resorcinol with 3-5 cc. of strong hydrochloric acid. A colorless, finely crystalline substance (m.p. 315°) was secured by Baker<sup>49</sup> by refluxing 2 mols of catechol with 3 mols of acetone for 48 hours in a mixture of acetic acid and concentrated hydrochloric acid. This was considered to be 5,6,5',6'-tetrahydroxy-3,3,3',3'-tetramethylbis-1,1'-spirohydrindene and to have the following structural formula

<sup>49</sup> W. Baker, *J.C.S.*, 1934, 1678.

It is believed that the 3 mols of acetone first unite to form phorone, which in turn condenses with the catechol. This was borne out by the fact that substitution of phorone for acetone in the preparation resulted in a similar end-product.

A procedure for the preparation of dihydroxydiphenyldimethylmethane (m.p. 150-154°C.) has been given by Beatty.<sup>50</sup> A mixture of 840 parts by weight of phenol, 175 parts of acetone and 74 parts of hydrochloric acid (sp.gr. 1.20) is allowed to stand at 30-40° until the entire mixture becomes solid. The crystals thus produced are washed with dilute acetic acid and, if necessary, recrystallized from water or dilute acetic acid and dried. To form a resin from this compound, 228 parts are then dissolved in 60 parts of hot 40 per cent formaldehyde solution and 2.28 parts of sodium hydroxide are added. The mixture is heated to 100°C. until the reaction proceeds to completion. A brittle resin is obtained, soluble in acetone, alcohol, amyl alcohol, amyl acetate, acetylene tetrachloride and strong alkali. Acidification of the alkaline solution gives a resin which is insoluble in alkali, linseed oil, turpentine and mineral oils. Longer heating produces a material insoluble in all solvents.

The reactions, according to Beatty,<sup>51</sup> are as follows:

Two molecules of this product then condense (the hydrogen of the phenolic hydroxyl uniting with the hydroxyl of the carbinol group) with the splitting out of water. Acids, alkalis or acid or basic salts may be used as catalysts. The process is varied by using other ketones in place of acetone and cresols instead of phenol.<sup>52</sup> Camphor, acetanilide, triphenylphosphate or alkyl derivatives of the benzenesulphonamides may be incorporated as plasticizers.<sup>53</sup> The products are intended for a variety of uses,<sup>54</sup> e.g., in varnishes,<sup>55</sup> in cellulose acetate compositions<sup>56</sup> for artificial silk filaments and fabrics made therefrom,<sup>57</sup> in films,<sup>58</sup> as a coating for films<sup>59</sup> or for the manufacture of sound records.<sup>60</sup>

A phenol-ketone resin made by McIntosh<sup>61</sup> was suggested for use in electrical insulation. Phenol and acetone or methyl ethyl ketone may be boiled under reflux with a catalyst (sulphuric acid, bromine, pyridine) until a gummy mass results. This is further heated at 120-130°C. to a shellac-like solid and then dissolved in a solvent (e.g., acetone or alcohol). Hexamethylenetetramine (5 per cent) is added and the solvent is removed by distillation. The resulting material is subjected to heat and pressure to convert it into an infusible form. Ketone-phenol

resins are said to form hard, resistive, odorless, lightproof bodies when mixed with such filling materials as chalk, dolomite, magnesia, alumina, metal oxides, asbestos, cellulose, wood or wool.<sup>62</sup>

Liquid resinous substances soluble in dilute alkalies were obtained by Amann and Fonrobert<sup>63</sup> on treating a hydroxyarylmethane (derived from the condensation of a ketone and a phenol) with an aldehyde in alkaline medium at 60-80°C. The resin, precipitated by addition of acid, was transformed into an insoluble infusible form by heating.

Terwilliger<sup>64</sup> recommended condensing a coal-tar fraction, boiling between 184-224°C., with an aldehyde, using an alkaline catalyst. Acetone, or light or heavy acetone oil, may be employed simultaneously. For example, a resin was prepared from 100 parts of coal-tar oil (b.p. 184-224°C.), 30 parts of acetone, 50 parts of paraformaldehyde and 3 parts of sodium hydroxide. The degree of condensation is regulated by the temperature to which the mixture is heated or by the duration of heating.

Walker<sup>65</sup> treated a phenol first with an aliphatic ketone and then with an aliphatic aldehyde, either or both reactions being carried out with alkaline catalysts. A white crystalline product was formed if, after the second step, acid was added to bring the  $p_H$  value to about 6. The product from phenol, acetone and formaldehyde had a melting point of 123-127°C.

Moss<sup>66</sup> used equimolecular proportions of phenol and acetone with hydrochloric, boric, phosphoric or sulphuric acid as catalysts to yield a resinous substance soluble in benzene, acetone and alcohol. The reaction was described as taking place in two stages; first, the formation of diphenylolpropane, recalling the product obtained by Dianin<sup>67</sup> and second, combination with the remaining acetone to give the resin. Diphenylolpropane (dihydroxydiphenyldimethylmethane) may also be condensed with ketones other than acetone, e.g., methyl ethyl ketone, diethyl ketone or chloracetone or with aldehydes. A direct union of 1 mol of diphenylolpropane with less than 2 mols of an aldehyde may also be made. For example when formaldehyde is used and condensation carried out at 110-130°C., a resin is formed with a melting point of 140-150°. Moreover, it can be heated to this temperature for a considerable time without overcondensation, thus permitting the unreacted substances to be driven off. The diphenylolpropane resins in general are said to be adaptable for use with cellulose esters and ethers in lacquers and adhesives, including cements for laminated glass. Diphenylolpropane<sup>68</sup> may be replaced by diphenylol-cyclohexane, this being accomplished by substituting cyclohexanone for acetone in the initial reaction.

The crude products obtained by the interaction of phenol with ketones were treated with a solution of an alkali or alkaline earth. The slightly soluble salt

which formed could then be separated, according to Koch and Guthke,<sup>66</sup> from the readily soluble phenolate derived from excess phenol in the reaction mixture.

Schuch<sup>70</sup> recommended mixing fusible condensation products from phenol and formaldehyde with cyclohexanone in an amount sufficient to combine with any free phenol and formaldehyde. A heat-hardening resin resulted. Braun, Anton, Haensel and Werner<sup>71</sup> obtained resinous products through the reaction of cyclohexanone with phenol and m-cresol, using hot hydrochloric acid. Diphenylolpropane-formaldehyde resin has been suggested for use in a cellulose acetate composition for coating rubber-insulated cables.<sup>72</sup> Irey formed the condensation product of a phenol and a ketone and treated it with formaldehyde in amounts of 0.1-0.4 mols for each mol of phenol in the initial reaction. By this means he secured a resin soluble in ordinary drying oils.<sup>73</sup> Hill and Walker<sup>74</sup> used o-cresol with ketones and aldehydes to give a similar product. Kraus<sup>75</sup> condensed phenol, acetone and formaldehyde with an alkaline catalyst to obtain resins that could be hardened by heat and pressure. A similar procedure is described by Süssenguth,<sup>76</sup> who further treats the resin with an acid (citric, phosphoric) to secure a heat-hardenable substance. He considers that diphenylolpropane formation does not take place in this case, but that a different type of material is synthesized. Finkelstein<sup>77</sup> and Steimmig<sup>78</sup> found that cyclic ketone resins are compatible with nitrocellulose, dissolving readily in glycol ethers, e.g., ethylene glycol methyl ether, and their esters.<sup>79</sup>

Mixtures of aromatic hydroxy compounds and cyclic ketones were heated with aldehydes in the presence of condensing agents by Schmidt and Seydel.<sup>80</sup> Resins were produced from phenol, cresol or  $\alpha$ -naphthol, cyclohexanone or methylcyclohexanone and 30 per cent formaldehyde, benzaldehyde or paraldehyde. Seydel and Roh<sup>81</sup> dissolved a mixture of phenol and cyclohexanone in benzene and subjected it to a current of dry hydrogen chloride. Bis-p-hydroxyphenyl-1,1-cyclohexane was formed and this compound, when dissolved in alcohol and treated with formaldehyde and concentrated hydrochloric acid, yielded a resin-like product melting at 180-200°C.

Mixtures of cyclic ketones and aromatic or hydroaromatic hydroxy compounds (e.g., cyclohexanol or phenol) may be condensed<sup>82</sup> in the presence of acid, alkaline or neutral condensing agents to obtain resins said to be stable to light, alkalies and acids, soluble in linseed oil and useful in the manufacture of lacquers.<sup>83</sup> A variety of products may be obtained by the condensation of phenols with  $\alpha$ - and  $\beta$ -unsaturated ketones.<sup>84</sup> With a phenol such as resorcinol, the yield is said to be almost quantitative. The substances formed varied in color with the different

constituents. For example, the compound from phenol and styryl methyl ketone is a gray powder, that from resorcinol and the same ketone is a yellow powder. Sen and Basu<sup>86</sup> studied the reaction between cyclohexanol-2-carboxylate and phenols. They found that ethyl cyclohexanone-2-carboxylate and resorcinol (with phosphorus pentoxide) yielded tarry resinous substances.

Diphenic anhydride and resorcinol, heated at 135-150°C. with zinc chloride, form an amorphous ruby red glass.<sup>87</sup> One reaction which is believed to take place is

According to Underwood and Clough,<sup>88</sup> this material contains resorcinoldiphenic and an amorphous condensation product derived from diphenyleneketone-4-carboxylic acid. Amorphous derivatives of the diphenic anhydrides from resorcinol and substituted diphenic anhydrides have also been described.<sup>89</sup>

#### UNSATURATED ALDEHYDES AND POLYHYDRIC ALCOHOLS

Resins can be made from phenols and unsaturated aldehydes. Acrolein,  $\text{CH}_2=\text{CHCHO}$ , is a dehydration product of glycerol,  $\text{CH}_2\text{OHCHOHCH}_2\text{OH}$ , and the two can, therefore, be logically considered in the same group. Darke and Lewis,<sup>90</sup> from a study of some of the resinification reactions of glycerol, conclude that the polyhydric alcohol is probably first converted to acrolein. Maksorov and Andrianov<sup>91</sup> report that when phenol and glycerol are condensed the glycerol appears to be first converted into acrolein and polyglycerides which then combine with phenol.<sup>91</sup> The condensations of phenol and unsaturated aldehydes such as acrolein, should therefore be considered first.

A hard, insoluble, non-conducting resin was produced by Moureu and Dufrasse<sup>92</sup> in a single operation by condensing phenol and acrolein with about 1 per cent of sodium hydroxide. Acrolein, they state, may be replaced by its polymerization products, for instance, a polymerized acrolein resin.<sup>93</sup> Kishi<sup>94</sup> reacted the aldehyde with phenol under 30 atmospheres pressure using as catalyst salts which give an acid reaction on being hydrolyzed (e.g., zinc chloride or aluminum chlo-

<sup>92</sup> The name "Acrolite" has been given to a resin made by J. McIntosh (*Ind. Eng. Chem.*, 1927, 19, 111) from phenol and glycerol. This name has taken on generic significance and would now probably include resins from phenol and acrolein also.

ride). From their work, Maksorov and Andrianov<sup>95</sup> concluded that the rate of condensation with an acid catalyst is at a maximum when 5 mols of acrolein to 1 mol of phenol are used, and with a basic catalyst when 25 mols of acrolein to 1 mol of phenol are employed. With an acid catalyst the rate of condensation is rapid at first, but slows up toward the end of the reaction, while with a basic catalyst the behavior is reversed. Xylenol-acrolein resins show a higher rate of conversion into an infusible and insoluble condition than do those from phenol and acrolein. They also have a higher melting point, as do the acrolein-cresol resins.

The use of other unsaturated aldehydes has been suggested also. For example, crotonaldehyde or aldol (which on distillation at atmospheric pressure loses water and becomes crotonaldehyde) or mixtures of both, can be reacted with phenols or nuclear methylated phenols or mixtures of these.<sup>96</sup> Polyhydric phenols, partially etherified, or creosote may be employed also. Mineral acids or compounds giving rise to hydrogen chloride (e.g., thionyl chloride) can be used as condensing agents. Carrying out the reaction in the cold gives rise to oils, while heating gives more resinous substances. Both types are soluble in most organic solvents and in caustic alkali, but are insoluble in alkali bicarbonate. The oily bodies dry in air, especially with drying agents, to films reported to be stable and weather-resistant. The product from phenol and aldol is a viscous oil having an iodine value of 130-160. A substitute for linseed oil is said to be derived from crotonaldehyde and creosote.

The oily materials can be treated with formaldehyde and condensing agents<sup>96a</sup> to yield more viscous though soluble forms, which can be rendered infusible and insoluble by heating under pressure. Balle and Wohlers<sup>97</sup> suggested that the acid-catalyzed condensation products of phenols with aldol or crotonaldehyde are adaptable for the production of oil varnishes. Steindorff and Balle<sup>97</sup> also combined resins of this type, while still soluble and fusible, with phenol formaldehyde resins to form insoluble and infusible compounds.<sup>98</sup> Herrmann and Deutsche<sup>99</sup> used crotonaldehyde together with polyphenols, such as resorcinol or pyrogallol, to prepare resinous materials.

A resin from phenol and glycerol is described by McIntosh.<sup>100</sup> It is said to possess a high luster and excellent heat-resisting qualities and to have all the desirable properties of the phenol-formaldehyde type of resin. The resin is obtained, according to McIntosh and Wolford,<sup>101</sup> by boiling 100 g. of phenol and 90-100 g. of glycerol with about 20 drops of sulphuric acid under reflux for 6-8 hours. The liquid is then subjected to a temperature of about 125°C. for further condensation. After 5 hours heating at 125°C. the product is still fusible and is soluble in alcohol, acetone and benzene. Following about 24 hours at this temperature it is insoluble in all the mentioned solvents and is infusible. The resin can be used for practically the same purposes for which phenol-formaldehyde resins are employed. Hardening agents suggested include hexamethylenetetramine, benzidine-acetone and sodium-acetone-bisul-

phite. To vary the procedure phenol is replaced by its homologues or substitution products and for glycerol epichlorhydrin, allyl alcohol, glycerol aldehyde, dihydroxyacetone can be substituted. Catalysts which have been found effective for the condensation include bromine, pyridine, sulphur monochloride and aniline hydrochloride.

A reaction product of glycerol and phenol was used by Coffey<sup>102</sup> as a binder for mica splittings. The resin is made by heating 100 g. of phenol, 70 g. of glycerol and about 1 cc. of concentrated sulphuric acid at 160-190°C., the reaction being considered complete when 3.5 parts of water have been distilled. The acidity of the resultant rubbery material is neutralized with sodium carbonate.

Aiken<sup>103</sup> reacted phenol and glycerol at 110°C. and added hydrogen chloride or, in some cases, concentrated hydrochloric acid to the mixture in order to take up the water formed during the reaction. Other substances such as anhydrous copper sulphate may be used to secure the same effect. The product is dehydrated and transformed to the infusible condition by heating with paraformaldehyde and ammonium carbonate. Glycerol may be replaced by other compounds, e.g., the glycols of ethylene, propylene, butylene or amylene. In place of ammonium carbonate in the second step, other catalysts suggested are sodium phenolate, calcium phenolate, sodium hydroxide, calcium oxide or potassium carbonate. In making a resin from phenol and polyhydric alcohols (e.g., glycerol) in the presence of a small quantity of sulphuric acid, Novotny and Romieux<sup>104</sup> provided means for removing the water from the zone of reaction as fast as it was formed.

Mixtures of phenols with glycerol and sulphonated fatty acids or naphtha sulphonic acids were heated at 120-140°C. in a process used by Petrov.<sup>105</sup> The viscous product is washed with water, neutralized with alkali, dehydrated and then heated with 40 per cent formaldehyde. The material is cooled, hydrochloric acid added and the mixture cast into molds and heated until sufficient hardness is obtained. Petrov and Schmidt<sup>106</sup> studied the formation of resins from phenols, glycerol and 4-12 per cent formaldehyde, using acid catalysts, e.g., sulphuric acid, sodium bisulphate and naphthene-sulphonic acids. The resins derived from phenol were reported to be free from phenolic odor. It was also stated that sodium bisulphate leads to a lighter colored resin, naphthene-sulphonic acids give a water-resisting product and that glycol cannot replace glycerol.

#### MISCELLANEOUS

Resins were made by Carter and Cox<sup>107</sup> by condensing an aliphatic dichloride, e.g., methylene dichloride, with a phenol in ammonium hydroxide solution. In this instance the chlorinated hydrocarbon and ammonia yield hexamethylenetetramine *in situ* which reacts with the phenol.<sup>108</sup> Thus, 5 cc. of phenol, 6.4 cc. of concentrated ammonium hydroxide and 2.4 cc. of methylene dichloride were heated in a closed vessel for 30 minutes at 180°C. The fusible soluble resins produced are kneaded with water to remove any ammonium chloride formed. The resin may be hardened with hexamethylenetetramine.

Solutions of ammonium chloride and hexamethylenetetramine obtained by heating methylene dichloride and ammonia together in aqueous solution can be boiled

under reflux with phenol to obtain a fusible resin.<sup>100</sup> A similar process has been described<sup>101</sup> in which the reaction is carried out in aqueous solution (under pressure) at 150-180°C. To obtain 4.6 kg. of a yellow resin sparingly soluble in alcohol and acetone, 4.8 kg. of methylene chloride, 6 kg. of phenol, 2 kg. of 24 per cent ammonium hydroxide and 26 kg. of water are heated together for 4-5 hours at 150-155°C. Sodium phenate was substituted by Prutton<sup>111</sup> for phenol in forming a condensation product with methylene dichloride. The resin obtained was a plastic gum when hot and a brittle solid when cold.

The preparation of fusible soluble resins from phenol and methylal,  $\text{CH}_3\text{OCH}_2\text{OCH}_3$ , is described by Carter and Coxe.<sup>112</sup> These are similar to the ones from phenol and formaldehyde, and are obtained by heating under pressure 3 mols of phenol with 2 mols of methylal for 1 hour at 180°C. using 0.05-0.1 per cent of hydrochloric acid as catalyst. The resins may likewise be rendered infusible by heating with hexamethylenetetramine or formaldehyde. The methylals can be made in satisfactory yield by heating sodium hydroxide, methylene chloride and the corresponding alcohol under pressure at 120°C. for 40 minutes.<sup>113</sup> Resins from phenol and methylal are obtained also by boiling the reactants under atmospheric pressure with 10-20 per cent of acid. One reaction mixture consists of 4.6 g. of methylal, 8.5 g. of phenol, 22.8 g. of water and 9.1 g. of sulphuric acid. Reaction is completed in the course of a few minutes.<sup>114</sup>

If solutions of paraform or trioxymethylene in mono- or polyhydric alcohols are heated with zinc oxide, alumina or aluminum hydroxide, a polymer of formaldehyde (melting at 98°C.) is obtained, according to Gebauer.<sup>115</sup> This product is a tallow-like solid, but liquefies at about 60°C. and is then miscible with most organic solvents. The use of solutions of the polymer for the production of phenol-formaldehyde resins has been suggested.

Considerable resinous matter was obtained by Huppmann<sup>116</sup> in the condensation of p-cresol methyl ether with p-benzoquinone. Similarly, allyl alcohol or an allyl ester and a phenol (e.g., o-cresol), using zinc chloride as catalyst, yield a resin said to be compatible with cellulose esters.<sup>117</sup>

Aliphatic or aromatic aldehydo-carboxylic<sup>118</sup> acids containing the carboxyl group either in the nucleus or the side chain may be condensed with phenols by the use of catalysts such as hydrochloric acid. For example, m-aldehydo-phenoxycetic acid may be melted with phenol and treated at 40-50°C. with concentrated hydrochloric acid. Stirring is continued until the mass is viscous. The acid is then washed out with hot water and the resulting soft product heated at 150°C. until a test portion solidifies to a hard resin.

In preparing  $\beta$ -resorcylaldehyde from diphenylformamidine and resorcinol at 100°C. and subsequent treatment with caustic soda solution, followed by acidification, Shoesmith and Haldane<sup>119</sup> found that a small amount of resin was also pre-

## Chapter 19

# Modified Phenol-Aldehyde Resins

## I. Oil-Soluble Resins

It has already been stated (Chapter 2) that the demand of varnish manufacturers for more durable and quicker-drying finishes has resulted in the substitution of synthetic resins for natural resins formerly used. The durability and resistance of phenol resins led to attempts to employ them in oil varnishes. Difficulty was encountered at first, since phenol resins in the final stage are insoluble in drying oils.<sup>1</sup> Although the partly-cured resins (Novolaks) are soluble, their properties alter in time<sup>2</sup> and such resins lack the permanent quality possessed by those of the final stage. Hence investigations have been directed with a good measure of success to the incorporation of modifying agents to yield oil-soluble phenol resins which impart the desired durability to varnish films. The result has been the production of some phenol-resin varnishes which are quick-drying<sup>3</sup> and which furnish tough, flexible coatings sufficiently resistant to heat, moisture, sunlight and alkalis.<sup>4</sup>

### NATURAL RESIN MODIFIERS

The earliest method employed for making phenol-resins oil-soluble was to fuse them with a natural resin (rosin or copals). The resulting products possessed certain disadvantages which limited their application. For instance, they dissolved only after long heating, which prevented their use with the easily-polymerized tung oil; and once dissolved, they precipitated on dilution with hydrocarbon thinners. The earlier products darkened easily on exposure to light and apparently

<sup>1</sup> However finely ground resins dispersed in tung oil have been recommended (E. Elbel and F. Seebach, U. S. P. 1,880,930, Oct. 4, 1932, to Bakelite G m b.H.; *Chem. Abs.*, 1933, 27, 616. German P. 509,425, 1927; *Chem. Abs.*, 1931, 25, 833. German P. 519,469, 1928; *Chem. Abs.*, 1933, 27, 1217). F. Seebach, U. S. P. 1,816,128, July 28, 1931, to Bakelite G m b.H.; *Chem. Abs.*, 1931, 25, 5584. Cf. J. M. Taylor, U. S. P. 1,848,913, Mar. 8, 1932, to Continental-Diamond Fibre Co.; *Chem. Abs.*, 1932, 26, 2879.

<sup>2</sup> See C. T. O'Connor, *Am. Paint J. Conv. Daily*, 1934, 18 (53E), 10; *Brit. Chem. Abs. B*, 1935, 69.

<sup>3</sup> It has been reported that the speed of drying and the hardness of phenol-resin varnishes are proportional to the melting point of the resin. See *Circ., Natl. Paint, Varnish and Lacquer Assoc.*, 1934, 471, 319; *Chem. Abs.*, 1935, 29, 364.

were not true compounds, since rosin could be detected in many of them by the Storch-Morawski reaction.<sup>6</sup> These shortcomings were largely eliminated in the more modern products, in many of which rosin esters and polycumarone were used.<sup>6</sup>

In making a natural-resin-modified phenol resin Berend<sup>7</sup> observed that the fusion must be carried to a well-defined end-point in order to obtain a satisfactory material for oil varnishes. The end-point is reached when test specimens dropped on a glass plate remain clear in the cold, are soluble in fatty oils, and do not precipitate from solution on the addition of benzene or turpentine. It was found that a 3-hour heating at 300°C. was necessary to accomplish this result.<sup>8</sup> The suggestion has been made that some rosin-modified phenol resins are improved if the volatile constituents of the natural resin are removed by distillation.<sup>9</sup> Thus, Spanish rosin is fused at 150°C. with cresol-formaldehyde resin and the mixture is heated at 250°C. for 200 hours. The resulting mass is distilled *in vacuo* to give a clear substance (m. p. 110-120°C.) with an acid number of 42.

Berend<sup>10</sup> transformed infusible, insoluble phenol-aldehyde resins to soluble, fusible materials by heating them with polycumarone or rosin. This principle has been utilized to convert molding scrap into varnish material.<sup>11</sup> The synthetic resin is heated with colophony to give a product soluble in benzene, turpentine and linseed oil.

Champetier and Laporte,<sup>12</sup> in order to determine the exact effect of the fusion of a phenol resin with colophony, carried out the process in various ways. Phenol was condensed with formalin in the presence of hydrochloric acid, the reaction being stopped at the moment of turbidity. The resin which was obtained was mixed with colophony and heated at approximately 300°C. in a carbon dioxide atmosphere or in an autoclave. These two methods were varied by refluxing the mixture initially, by heating the rosin first at 90°C., or by distilling the product after fusion. It was found that free phenol is susceptible to esterification with abietic acid under these conditions, and that the rate of reaction increases rapidly as the temperature is raised above 285°C. Resin ester in the product increases the solubility in oil but lowers the fusion point. Also the solubility is improved by increase in the proportion of rosin but is decreased by the acids catalyzing the condensation or esterification. Prolonged heating at elevated temperatures decreases the acid number and raises the fusion temperature.

Pistor<sup>13</sup> found that an acid interchange took place when fatty acid glycerides were heated with either natural or oil-soluble synthetic resins. He considers that a distinct advantage is derived by the employment of neutral Albertol resins, since only a small amount of fatty acid is liberated as compared with the quantity yielded by copal or colophony.

It has been stated by Dupont and Man-Tcheung<sup>14</sup> that in making a rosin-modified phenol resin the best results are obtained by employing a condensation product from equimolecular proportions of phenol and formaldehyde (catalyzed with 1 per cent hydrochloric acid). Thirty parts of this resin are fused with 70 parts of rosin at 120-130°C., then 0.4 per cent of calcium oxide is added and the temperature is raised and maintained at 290°C. until the product is completely oil-soluble.

Oil-soluble resins for varnishes have been obtained by fusing the condensation product of salicylic acid and formaldehyde with rosin. The original object of this procedure was to raise the melting point of rosin and not to obtain a modified phenol resin.<sup>15</sup> Other modified resins include phenol-aldehyde condensation products fused with benzoic, salicylic, palmitic or oleic acid<sup>16</sup> and mixed phenol-aldehyde-alkyd resins fused with colophony.<sup>17</sup>

In addition to fusing natural resins with phenol-aldehyde condensation products, attempts were also made to incorporate the natural resin directly in the initial condensation. Albert and Berend<sup>18</sup> reacted phenol and formaldehyde in the presence of 5 per cent of natural resins, which act as catalysts. Some of the resinous bodies thus formed were oil-soluble and could be saponified.<sup>19</sup> Later it was discovered that only when the rosin, balsams, or similar materials were used in quantities greater than required for their action as catalysts would the product be soluble in oil.<sup>20</sup> The process allows any free phenol remaining to be combined with formaldehyde which may be added later. A mixture of 100 grams of phenol, 100 grams of rosin, and 30 grams of trioxymethylene is heated under reflux at 115-120°C. for 6 hours. The temperature is then raised to 200°C. and the reaction mass stirred to remove volatile constituents.<sup>21</sup> A more soluble material is obtained when 95 g. of phenol, 70 g. of 40 per cent formaldehyde, and 2 g. of hydrochloric acid are heated for 6 hours with 30 g. of Manila copal. The use of a basic catalyst has also been suggested in this procedure,<sup>22</sup> but prolonged heating yields an insoluble substance. The procedure has been further modified by heating the resin or resin acid of copaiba balsam with phenol, and then adding formaldehyde and hydrochloric acid.<sup>23</sup>

Promising results were obtained with a phenol-formaldehyde-colophony condensation product in coatings for the protection of ship-bottoms from marine growths. The effect may be due to the presence of free formaldehyde or phenol bodies, which have a toxic influence.<sup>24</sup>

Japanese lac has been proposed as a modifier.<sup>25</sup> An intimate mixture of 100 parts of phenol, 200 parts of formalin and 50 parts of Japanese lac were heated

for 48 hours at 120°C. The residue, after distillation and separation of the excess formaldehyde, is an oil-soluble resin.

After incorporation of rosin, phenol-formaldehyde resins may be esterified with glycerol.<sup>26</sup> The product obtained is more soluble in drying oils, has a greater molecular weight, and yields solutions of greater viscosity. Compared with ester gum, it possesses more resistance to alkali and weathering influences. The preparation is as follows: 100 parts of cresol are heated with 400 parts of rosin and 40 parts of paraformaldehyde until the cresol has entirely disappeared and a tough resinous mass which remains clear in the cold is produced. The resin is dehydrated

phthalate or benzyl acetate,<sup>32</sup> or with a metallic soap or rosin or of a fatty acid.<sup>33</sup>

Rosenblum<sup>34</sup> employed resin esters to modify phenol-aldehyde resins. His method is as follows: 100 parts of cresol, dissolved in 100 parts of turpentine, are heated at 100°C. with 100 parts of 40 per cent formaldehyde until reaction is complete. After separation of water by distillation, 100 parts of the resulting solution are heated with 120 parts of a mixture of 25 per cent glyceryl diacetate and 75 per cent glyceryl triacetate.<sup>35</sup> The resin, after removal of volatile constituents by distillation, has an acid number of 10 or less. A variation of the procedure includes the addition of the resinates or oleates of zinc, calcium or barium.<sup>36</sup> Cracked rosin may be substituted for the ordinary rosin.<sup>37</sup> In another instance, the condensate from p-phenyl phenol, zinc acetate and formaldehyde is heated with rosin ester gum.<sup>38</sup>

A resin-ester-modified phenol resin was made by Binapfl<sup>39</sup> by condensing colophony with crude cresol in the presence of boron fluoride, esterifying the product with glycerol and then treating with paraformaldehyde. Natural resin esters may be hardened by treatment with synthetic resins.<sup>40</sup> For example, 100 parts of phenol-dialcohol and 100 parts of paraldehyde-phenol condensation product are melted together, and 800 parts of rosin-glycerol ester are added. The mass is heated for several hours, first at 150°C. and then at 250°C. Heating is continued until the melting point is constant. The product formed has its melting point raised from 68° to 100°C. and is soluble in linseed oil.

Neutral resin esters are prepared by esterifying a mixture of natural or synthetic resin acids and compounds containing the hydroxyl group, the resin acid and hydroxyl-containing substances being present in equivalent proportions.<sup>41</sup> For example, a phenol-aldehyde resin is melted in glycerol and rosin is added. The reaction is catalyzed with boric acid. Similarly the condensation product of cresol hydroxymethyl ether and formaldehyde heated at 200-250°C. with rosin gives a resin with a low acid number.<sup>42</sup>

A resinous mixture for lacquers was obtained by Bielouss<sup>43</sup> by esterifying a phenol-formaldehyde-rosin condensation product with glycerol and then forming in the resultant mass a second synthetic resin from glycerol and phthalic anhydride.<sup>44</sup> In a process employed by Balle,<sup>45</sup> a rosin-modified phenol resin containing

excess resin acid is treated with acetylene in the presence of mercuric sulphate to yield a hard resin soluble in hydrocarbons.

For the preparation of varnishes, tung oil may be heated with boric or oxalic acid, which allows polymerization but retards gelatinization. The treated oil is then incorporated with an oil-soluble phenolic resin to give a coating composition.<sup>44</sup>

The reaction between drying oils and oil-soluble resins, at least in the case of Amberols and tung oil, is considered to be one of chemical combination.<sup>45</sup> Mixed esters are apparently formed and the varnish film can be regarded as a synthetic resin. Viscosity measurements during cooking of tung-oil-resin varnishes indicate that chemical polymerization (or condensation) first occurs, followed by physical aggregation or gel formation.<sup>46</sup>

One form of Albertol resin has been used for testing tung oil varnishes. The "Albertol number"<sup>47</sup> is defined as the per cent by weight of Albertol 111 L that must be added (as 50 per cent solution in benzene) to tung oil (containing 0.1 per cent of cobalt as resinate), to yield a non-frosting film when dried in an oven (English Standard Specification 256). Brendel suggested use of other resins in this test and recommended that the term "frosting number" be used.<sup>48</sup>

After investigations as to the effect of driers on Amberol-linseed oil varnishes, Sward and Gardner<sup>49</sup> made the following generalizations: Fastest drying was obtained by the addition of 0.5 per cent lead linoleate and 0.2 per cent manganese linoleate. Large amounts of driers tend to produce brittleness and do not accelerate drying. Manganese driers reduce the elasticity of the films and induce skinning on storage to a greater extent than the lead or cobalt compounds.

Although most of the oil-soluble resins are used in the making of varnishes,<sup>50</sup> they may also be employed in the manufacture of linoleum,<sup>51</sup> printing inks,<sup>52</sup> imitation leather finish,<sup>53</sup> adhesives,<sup>54</sup> transfer and marking compositions,<sup>55</sup> coatings for cans,<sup>56</sup> coatings for paper,<sup>57</sup> and plastic mixtures for insulation.<sup>58</sup> An aluminum salt

of a high-acid Albertol resin has been investigated and suggested as a flattening-medium for varnishes.<sup>61</sup> A short-oil Albertol-tung oil varnish has been recommended as a water-resistant priming coat.<sup>62</sup> Another varnish which has been suggested is made by melting an Amberol resin with  $\beta$ -eleostearin at 210°C.; lead oxide and manganese dioxide are added and the temperature raised to 275°C. High-boiling gasoline is used as the solvent.<sup>63</sup>

The use of Albertol resins in nitrocellulose lacquers is recommended because of their neutrality, purity and uniformity, as well as the conferment of increased alkali resistance. They are soluble for the most part in solvents for such lacquers (acetone, amyl or ethyl acetate, Cellosolve, xylene or turpentine). Combination lacquers (oil and nitrocellulose) present another field of use. Because the Albertols (Amberols) are hard resins, a plasticizer is advisable.<sup>64</sup>

### OIL-MODIFIED PHENOL RESINS

In the search for oil-soluble phenol resins it was observed that the desired properties are obtained not only by incorporation of natural resins but also by the use of drying oils as modifiers. Tung oil is the most widely employed oil for this purpose.

One method of producing an oil-modified phenol resin is described by Brown.<sup>65</sup> Twelve parts of raw tung oil and 15 parts of a lead and manganese-tungate and-resinate drier are heated in an open kettle to 180-190°C. as rapidly as possible and maintained at that temperature for about 15 minutes. The liquid is allowed to cool to 100°C. and 4 parts of cresol and 3 parts of 40 per cent formaldehyde solution are added. The temperature of the mixture is maintained at 95-100°C. for 1 hour with stirring, this treatment effecting evaporation of most of the water. Heating is then stopped and the mixture is permitted to stand for several hours. Precipitated sediment is removed and the temperature is raised to nearly 150°C. until the odor of formaldehyde has disappeared. The material is thinned with kerosene or turpentine to form a baking varnish. The use of a smaller proportion of tung oil results in the formation of a product which may be used for the impregnation of cloth and fiber.<sup>66</sup> The procedure may be altered by heating the tung oil and phenol together, adding later the aldehyde and drier.<sup>67</sup> By varying the proportions and omitting the drier, a plastic composition for insulation is obtained.<sup>68</sup>

The reaction of oxidation products of linseed oil or of tung oil with phenol and formaldehyde, employing a basic catalyst such as ammonia, yields a resin which is said to be resistant to acids.<sup>69</sup> It is soluble in toluene and xylene and may be used in the insulation of electrical apparatus.<sup>70</sup> The product obtained by the interaction of 100 parts of cresol, 100 parts of tung oil, and 20 parts of hexamethylenetetramine is soluble in turpentine, and with driers forms a resistant film at room temperature.<sup>71</sup> Combination of phenol, or cresol, formaldehyde

and tung oil is effected by heating the mixture at 100-150°C. A catalyst is not necessary, but use of a closed vessel enables the reaction to be carried out under pressure. Bodied tung oil may replace the raw oil. Dehydration is accomplished by subjecting the condensate to a vacuum at 100°C. or less. Varnishes made by this method give coatings which, after baking, are reported to have exceptional toughness, flexibility and dielectric strength.<sup>72</sup> Similarly, the reaction of xylolol

with paraformaldehyde in tung oil in the presence of triethanolamine as a catalyst yields a substance which may be dissolved in naphtha.<sup>73</sup>

An oil-modified resin described by Croad<sup>74</sup> is prepared by condensing 2 mols of a phenol (e.g., cresylic acid) with 1 mol of formaldehyde in a solution (e.g., sodium acetate) which is only slightly alkaline to alizarin-red S and then heating the product with tung or linseed oil.

Byck<sup>75</sup> has made a coating composition by boiling 100 parts of phenol, 150

parts of tung oil and 2 parts of phosphoric acid under reflux for 6 hours. The addition of 10 parts of dry hexamethylenetetramine gave a non-reactive resin which was dissolved in 150 parts of turpentine. An additional 10 parts of hexamethylenetetramine were mixed with the solution. The composition yields adherent and resistant coatings when baked on wood or metal. Or it may be used to coat regenerated cellulose films or threads to give insulating material.<sup>70</sup> Plastics for electrical insulation are formed by employing the same reaction with different proportions of reacting materials.<sup>71</sup> These products may also be used as binders for abrasives in grinding-tools,<sup>72</sup> or, dispersed in tetrahydronaphthalene, as an ingredient in printing ink,<sup>73</sup> or mixed with gelatinizable cotton flock as a molding composition.<sup>74</sup>

Modification of the above-mentioned coating composition by the addition of other resins gives a film which dries quickly without the aid of heat.<sup>75</sup> For example, 100 parts of formalin and 50 parts of rosin are added to the non-reactive resin obtained by Byck. The solution is heated under reflux for 5 hours and finally boiled until the water has evaporated. The resin when dissolved in turpentine or toluene gives an air-drying varnish. Incorporation of 5-10 per cent cellulose nitrate or other esters with a solution of the resin just described has been suggested.<sup>76</sup>

The combination of drying oil and rosin as a modifier was also recommended by Mabey.<sup>77</sup> The initial condensation product of 100 parts phenol and 100 parts aldehyde was heated at about 100°C. with rosin (100 parts) and tung oil (6-50 parts) until a homogeneous mass was formed.

Another variation has been proposed by Delaney.<sup>78</sup> To a dehydrated viscous cresol-formaldehyde-tung oil condensation product is added chlorinated naphthalene and the material is heated under reflux until an intimate mixture is obtained. Toluene and xylene are incorporated to form a varnish.

Colloidal dispersions of phenol-oil-formaldehyde resins in butyl alcohol have been employed where varnishes of low penetrative power are required.<sup>79</sup> For the same purpose, Courtney<sup>80</sup> has recommended an emulsion of an oil-synthetic resin varnish in water. A phenol-acetaldehyde condensation product dissolved in oil with the addition of hexamethylenetetramine is used as a binding agent for 1930, 24, 4175. British P. 358,603, 1930; *Chem. Abs.*, 1932, 26, 4970. French P. 700,063, 1930; *Chem. Abs.*, 1931, 25, 3503. A varnish of this nature is suggested for waterproof backings for adhesive tape. <sup>80</sup> R. P. Courtney, U. S. P. 1,987,549, Jan. 8, 1935, to Bakelite Corp.; *Chem. Abs.*, 1935, 29, 1639.

laminated stock such as paper or asbestos.<sup>87</sup> Still another method of obtaining a heat-hardenable resin dissolved in a drying oil has been given.<sup>88</sup> A mixture of Novolak and linseed oil is heated to 300°C. After cooling to 100°C., 3 per cent of hexamethylenetetramine is added and heat again applied. The resulting material hardens at 120°C. within a day.

Potentially reactive phenol-aldehyde resins when heated at 150°C. with oxidized drying oils in a mutual solvent (e.g., cyclohexanol) give on evaporation of the solvent a viscous mass. This, mixed with turpentine, affords a satisfactory varnish film.<sup>89</sup> The presence of iodine accelerates the reaction.<sup>90</sup> An analogous procedure is that suggested by Drummond and Morgan.<sup>91</sup> A phenol and an aldehyde are allowed to react in a volatile solvent and an oil later incorporated. For example, 32 parts of cresol are condensed with 14 parts of formaldehyde in butyl alcohol containing sodium hydroxide. The product is acidified with boric acid and distilled until the boiling point indicates that all the water has been removed.<sup>92</sup> Then 32 parts of tung oil are added and distillation continued until a drop of the solution dries clear.<sup>92a</sup> Material which has been prepared in this manner may be treated with acetic anhydride to give a rapid-drying coating.<sup>93</sup> For instance, 100 parts of resol are allowed to react with 100 parts of tung oil in the presence of 200 parts of cyclohexanol. Most of the solvent is distilled off *in vacuo* and 100 parts of acetic anhydride are added. After the solution is boiled for about 2 hours, the acetic acid formed and the unconverted acetic anhydride are removed as completely as possible by vacuum distillation. The residue is redissolved in cyclohexanol (recovered in the first step of the operation) and the solvent again removed by distillation. The purpose of this procedure is to eliminate the last traces of acetic anhydride. The resin is soluble in an alcohol-benzene mixture, in benzene or in turpentine.

Polyhydric alcohols which have been partially esterified with a drying oil acid may be condensed with an aldehyde and a phenol.<sup>94</sup> Thus resorcinol, paldehyde, tung oil monoglyceride, butyl alcohol and a solution of sodium hydroxide in methylated spirit are heated together. The product diluted with butyl alcohol serves as a varnish.

Condensation of phenol and formaldehyde may be effected by adding hot linseed (or castor) oil to a cold, well-stirred aqueous solution of the reactants.<sup>95</sup> On standing, the mixture separates into two portions, a lower water layer and a

<sup>92</sup> H. F. Wakefield (U. S. P. 1,997,614, Apr. 16, 1935, to Bakelite Corp.) suggests that reaction between formaldehyde and phenol-tung oil condensate be effected in high-boiling solvents such as butanol, amyl alcohol, or Cellosolve. Water formed during reaction forms a constant-boiling mixture with the solvent and may be removed as such.

<sup>92a</sup> The drying rate of phenol-resin varnishes is accelerated by adding mixtures of castor oil or tung oil with salts of a dehydrating nature, e.g., the chlorides of iron, zinc, tin, aluminum or calcium. supernatant oil layer. The latter may be decanted and further thickened by heating. If the last operation is carried too far, the hardness of the product may be reduced by the addition of phenol. Reaction between a mixture of 4 parts of naphthol and 50 parts of oxidized castor oil and a mixture of 2.5 parts of hydrochloric acid and 20 parts of formalin at 100°C. yields an elastic body.<sup>96</sup> A resinous material for dressing fabrics was secured by heating equivalent amounts of castor oil and resorcinol below 100°C. Sulphuric acid served as the catalyst.<sup>97</sup>

Phenol-aldehyde condensation products which contain 20 per cent tung oil are soluble in ketones, alcohols, and esters. They can be made soluble in hydrocarbons by heating at 150°C. according to Drummond and Morgan.<sup>98</sup>

*Courtesy Buffalo Foundry & Machine Company*

FIG. 69.—Vacuum-Pressure Impregnating Kettles. The material to be impregnated is placed in the middle container and is dried under vacuum. The right-hand container is filled with a solution of the resin used for impregnation. Upon opening the connecting valve between the two vessels the solution floods the middle vessel. Air pressure can be applied to force the solution into the pores of the material which is being impregnated.

It has been stated that phenol-oil-formaldehyde resins can be employed to improve the strength and wear-resisting qualities of fire hose, rubber tires, or other rubber-coated fabrics.<sup>99</sup> The fabric is first impregnated with the resin and then coated with rubber. Stencil paper is made by coating yoshino paper with a solution of phenol-tung oil-formaldehyde resin, aluminum stearate, and butyl phthalate. The paper is then heated at 140°C. to polymerize the resin.<sup>100</sup>

Tests made on plain and parkerized (treated with phosphoric acid) iron plate, which were coated with a primer, and a suspension of lampblack in a tung oil-phenol-formaldehyde resin, and dipped in a 3 per cent sodium chloride solution, showed that the attack was greatest at the air-liquid interface. Resistance de-

creased with increasing oil content.<sup>101</sup> For insulating copper wire, Ruben<sup>102</sup> employed a phenol-oil-formaldehyde resin (in a very thin film) to act as a binder for a coating of insulating oxides such as those of titanium, chromium or iron.

### OTHER OIL-SOLUBLE RESINS

Although real success was achieved in the search for oil-soluble phenol resins by modifying them with drying oils or with natural resins, some need was shown for producing oil-soluble resins directly without such modification. As will be seen from the discussion that follows, this need was filled partially by the use of phenolic substances other than ordinary phenol.<sup>103</sup>

Some of the first unmodified oil-soluble resins were produced from the condensation of formaldehyde with o-cresol<sup>104</sup> or p-cresol.<sup>105</sup> Others have been obtained by allowing acetaldehyde<sup>106</sup> to react with tar oils<sup>107</sup> or with phenol in carbon tetrachloride and catalyzed with hydrochloric acid.<sup>108</sup> The use of phenols of high molecular weight also yield the desired products.<sup>109</sup> Substances soluble in aromatic hydrocarbons, turpentine, and fatty oils have been made by heating a phenol ether (e.g., anisole or  $\beta$ -naphthol ethyl ether), with formaldehyde in the presence of a strong organic acid (formic) or an inorganic salt with an acid reaction (zinc chloride).<sup>110</sup> Condensation has also been carried out with the methyl or ethyl ether of 1,3,5-xylenol.<sup>111</sup> Coating compositions are made from the resultant product by incorporation with drying oils or nitrocellulose.

The addition of diazotized p-nitroaniline to a molten mixture of 94 parts of phenol and 7.5 parts of hexamethylenetetramine gives an oil-soluble dyestuff.<sup>112</sup> On cooling, the mass is converted into a solid metallic-green- or orange-colored azo resin, which gives orange-colored solutions in oils and fats.

When the reaction between phenol and formaldehyde is carried out in the presence of a terpenic or alicyclic alcohol such as  $\alpha$ -terpineol, a fusible resin soluble in oils results.<sup>113</sup>

Varnish resins of the oil-soluble type are obtained by the reaction of xylenols with paraformaldehyde, according to Drummond and Morgan.<sup>114</sup> For example 976 parts of mixed xylenols, 150 parts of paraformaldehyde, 30 parts of concentrated hydrochloric acid and 1000 parts of methyl alcohol are boiled together for 20 hours. The product is distilled at 120°C. until the residue becomes hard on cooling. The latter may be dissolved in an equal weight of tung oil by heating at 175°C. for 2 hours and used with solvent naphtha as a varnish. Later work indicated the fractions

<sup>106</sup> Apparatus especially adapted for the production of phenol-aldehyde-type oil-soluble resins is described by A. Johnson, U. S. P. 1,994,714, Mar. 19, 1933, to Combustion Utilities Corp. Provision is made for the immediate return to the reaction kettle of volatilized low-boiling ingredients (e.g., acetaldehyde) and their thorough intermixture with the less volatile liquids. A better control of the process is thus ensured, with less danger of the formation of an oil-insoluble product.

of low-temperature tar boiling above 230°C. yield resins which may be incorporated in tung oil,<sup>115</sup> or alternatively the phenolic fraction (100 grams) boiling at 255-275°C. may be condensed with paraformaldehyde (40 grams). When the mixture is heated, a vigorous reaction occurs at 110-120°C.; and further heating is necessary until a clear melt is obtained. More aldehyde should be added at this point to combine with unreacted phenol. The resultant brown resin has a melting point of about 150°C. Other investigators<sup>116</sup> have incorporated fatty acids in the reaction of xylenols or higher phenols with formaldehyde.

The preparation of oil-soluble resins from cresylic acid and formaldehyde is described by Novak.<sup>117</sup> Three parts each of cresylic acid and commercial 40 per cent formaldehyde are mixed with 1 part of ammonium hydroxide (sp.gr. 0.898). After the reaction has been completed, which may take 30-60 minutes, the aqueous layer is decanted. The product obtained contains 3-5 per cent nitrogen according to Novak. It is converted into a varnish by heating with two-thirds its weight of tung oil at 90-100°C. The resulting solution is used to impregnate cloth, fibers or paper to form insulating material. It is stated that the varnish heat-hardens very quickly to an infusible state.

It has been noted that crystalline condensation products obtained from  $\beta$ -naphthol and formaldehyde are made oil-soluble by heating them above their melting points. A solution of such substances in fatty oils is said to give good varnishes.<sup>118</sup> Similarly a fusible phenol-aldehyde resin may be heated with a polynuclear phenol to yield a material that is oil-soluble.<sup>119</sup> For example, 100 kilos of reactive resin are fused with  $\beta$ -naphthol and heated for 1.5 hours at 260°C. If manganese oxide or lead oxide is used as a catalyst, the resin is more soluble in oil, and the varnish dries more quickly. Addition of natural resins such as rosin, dammar, and copal facilitates solution in oils.<sup>120</sup>

According to Seebach<sup>121</sup> the same procedure is applicable to infusible phenol resins. Equal parts of resite and dihydroxybiphenyl are heated together until the resin is dissolved and no more water vapor is driven off. The resulting product is readily soluble in hot fatty oils.

Investigations of the effect of  $\beta$ -naphthol on the drying rate of an oil show that it accelerates the rate at elevated temperatures in sunlight. However retardation takes place in indirect light, unless a drier is present. The drying of varnishes made from tung oil and an acid or neutral resin is retarded or accelerated respectively by  $\beta$ -naphthol; but if a drier is also present, retardation is usually observed.<sup>122</sup> The addition of 0.3-1 per cent of cresol to an oil varnish is said to prevent skinning.<sup>123</sup> Merkle<sup>124</sup> noted that the presence of an oxidation catalyst (manganese or lead) and an inhibitor (eugenol or  $\alpha$ -naphthol) in drying-oil compositions prevents their oxidation in bulk without retarding their normal drying rate in thin films.

Condensation of hydroxybiphenyls with formaldehyde in the presence of fatty

oils yields oil-soluble resins.<sup>125</sup> A mixture of 100 parts of p-hydroxybiphenyl<sup>126</sup> and 100 parts of formalin are heated until a resin forms. This is heated with 100 parts of tung oil at 210°C. until a small portion remains clear on cooling and can be diluted with cold linseed oil. Addition of more oil, while keeping the temperature above 200°C., a thinner, and a drier gives a varnish. This composition, or one made from the resin prepared by Byck,<sup>127</sup> is said to be superior to a varnish containing ester gum in that it dries more quickly, the films are harder, more elastic, and more durable.<sup>128</sup> (See Figs. 70 and 71).

The data for the curves were obtained from a mixture of 1 part resin and 2 parts tung oil. Elasticity was determined by the standard test of adding Kauri

FIG. 70.

Drying-Time of Varnishes and Durability of Films Prepared from Mixtures of Ester Gum and Oil-Soluble Phenol Resin. (V. H. Turkington.)

gum and finding the amount of such addition necessary to produce cracks on bending around a 3 mm. rod after baking 5 hours at 95°C. The durability rating indicates the relative freedom from cracks or other signs of failure after exposure of test panels. Hardness figures were obtained with a swinging-beam apparatus.

Coatings made in the same manner, except that air was bubbled through the mixture during heating, are recommended for treating floor coverings.<sup>129</sup>

<sup>125</sup> V. H. Turkington and W. H. Butler, British P. 347,737, 1929, to Bakelite Corp.; *Chem. Abs.*, 1932, 26, 1812. French P. 689,014, 1930; *Chem. Abs.*, 1931, 25, 1109. German P. 571,039, 1930; *Chem. Abs.*, 1933, 27, 2831. Cf. French P. 716,510, 1931; *Chem. Abs.*, 1932, 26, 2333.

<sup>126</sup> Hydroxybiphenyls are prepared from the corresponding chlorobiphenyl by hydrolysis with aqueous sodium hydroxide under pressure at 250–300°C. employing a copper catalyst (E. C. Britton, U. S. P. 1,959,283, May 15, 1934, to Dow Chemical Co.; *Chem. Abs.*, 1934, 28, 4433). R. W. Rittler (German P. 605,520, 1934, to Chemische Fabrik von Heyden A.-G.; *Chem. Abs.*, 1935, 29, 1836) recommends separation of o- and p- forms of hydroxybiphenyls by treatment with aqueous solutions of alkaline earth salts, hydroxides or oxides and filtering. o-Hydroxybiphenyl is soluble and may be precipitated from the filtrate by acidification. Phenol and chlorocyclohexane react at 300°C. to give o- and p-cyclohexyl phenol (E. C. Britton and R. P. Perkins, U. S. P. 1,862,075, June 7, 1932, to Dow Chemical Co.; *Chem. Abs.*, 1932, 26, 4068). The latter compound when heated with a dehydrogenating catalyst yields o- or p-phenyl phenol (E. C. Britton and S. L. Bass, U. S. P. 1,862,000, June 7, 1932, to Dow Chemical Co.; *Chem. Abs.*, 1932, 26, 4068).

<sup>127</sup> L. C. Byck, U. S. P. 1,590,079, June 2, 1926, to Bakelite Corp.; *Chem. Abs.*, 1926, 20, 3090. This has been discussed previously in the chapter.

<sup>128</sup> V. H. Turkington and W. H. Butler, U. S. P. 1,988,615, Jan. 22, 1935, to Bakelite Corp.; *Chem. Abs.*, 1935, 29, 1667. British P. 378,094, 1931; *Brit. Chem. Abs.*, B, 1932, 997. V. H. Abs.*, 1935, 29, 363.

<sup>129</sup> V. H. Turkington, U. S. P. 1,988,616, Jan. 22, 1935, to Floor Covering Patents, Inc.; *Chem. Abs.*, 1935, 29, 1667.

In a somewhat analogous procedure<sup>120</sup> a mixture of  $\alpha,\alpha(4,4'$ -dihydroxy-3,3'-dimethyldiphenyl) cyclohexane, or  $\beta,\beta(4,4'$ -dihydroxy-3,3'-dimethyldiphenyl) propane, and formaldehyde is condensed in the presence of hydrochloric acid and denatured alcohol. The product may be dissolved in tung oil to give a varnish.

The reaction of a phenol with a ketone yields a compound which is converted into an oil-soluble resin by treatment with formaldehyde.<sup>121</sup> Equimolecular amounts of phenol and acetone, using hydrochloric acid as a catalyst, form  $\beta,\beta$ -bis(4-hydroxy-phenyl) propane and a condensation product of acetone with

FIG. 71.  
Hardness and Elasticity of Varnish Films Containing Mixtures of Oil-Soluble Phenol Resin and Ester Gum. (V. H. Turkington.)

the latter. The mixture is refluxed for 8 hours with a 40 per cent solution of formaldehyde (0.35 mol per mol of phenol used in the first reaction). Water and excess formaldehyde are removed by distillation *in vacuo*. at 200°C. The resulting resin has a melting point of 100-110°C. and is soluble in tung and other oils.

In some instances oil-soluble resins are made by condensation of aldehydes with phenols containing an alkyl or aryl group in the para position. Such phenol derivatives are obtained by heating alcohols with phenols in the presence of zinc chloride or other dehydrating agents.<sup>122</sup> Thus by heating isobutyl alcohol and phenol, the following reaction occurs:

P. 1,887,662, Nov. 15, 1932, to Sharp & Dohme, Inc.; *Brit. Chem. Abs. B*, 1933, 999.

Phenols can be alkylated with an alkyl halide in the presence of zinc or ferric chloride,<sup>133</sup> or of alcoholic potassium hydroxide.<sup>134</sup> The reaction will also take place with an unsaturated hydrocarbon such as isobutylene both with<sup>135</sup> and without<sup>136</sup> metallic halides as catalysts. Thomas<sup>137</sup> has made p-tertiary amyl phenol by allowing phenol to react with amylene in the presence of sulphuric acid. Similarly octenes, obtained from the isomeric butenes, react with phenols or phenyl ethers in the presence of sulphuric acid to give the corresponding alkylated compound.<sup>138</sup>

Analogous aryl-substituted phenols such as triphenyl-p-hydroxy-phenyl-methane [ $(C_6H_5)_3CC_6H_4OH$ ] have been prepared by elimination of water between triphenylcarbinol and phenol<sup>139</sup> and by the Friedel-Crafts reaction, using triphenyl-chloromethane and phenol.<sup>140</sup>

The preparation of resins with p-alkylated phenols is described by Hönel.<sup>141</sup> Eighty-two g. of p-tertiaryamylphenol, 90 g. of 30 per cent formaldehyde, and 75 cc. of 3N sodium hydroxide are dissolved by gentle warming and heated at 50-55°C. for 24 hours. The viscous oily reaction product is precipitated with an acid, separated from the supernatant liquid, and dried. The resultant resin is fast to light and soluble in oils.<sup>142</sup> The reaction may also be carried out in an acid medium.<sup>143</sup> Hönel<sup>144</sup> has treated these compounds with esters to form materials for impregnating and coating. For example, 6 parts of melissic palmitate (beeswax) were melted and stirred with the liquid condensate obtained from 1 part of p-tertiaryamylphenol and 1 part of 30 per cent formaldehyde. The temperature was gradually raised to 240°C. The brown end-product was harder than beeswax, more plastic, and surfaces coated with it were more easily polished. It is contended that p-substituted phenol resins go quite slowly into the infusible state. Better control of the reaction is thus permitted and an advantage in the preparation of oil-soluble bodies is indicated.<sup>145</sup>

Cyclohexyl phenol may be used instead of an alkylated phenol in the condensations just discussed.<sup>146</sup> For example, p-cyclohexyl phenol is heated with formaldehyde and oxalic acid. The product heated with tung oil and dissolved in solvent naphtha gives a coating composition. It may also be dissolved with nitrocellulose

in a mixture of toluene, butyl and ethyl acetate, and butyl alcohol with tritolyl phosphate to form a lacquer.

The heavy-metal salts of oil-soluble phenol aldehyde resins have been suggested as siccatives for paints and varnishes.<sup>147</sup> To prepare these salts, phenol-acetaldehyde condensation products are heated with aqueous sodium hydroxide until saponification is complete. Subsequently treatment with hot lead acetate solution precipitates the lead salts, which are separated, dried and dissolved in turpentine. Alternatively, the condensation product may be heated with cobalt acetate until the evolution of acetic acid has ceased.

The use of raw oil rather than heat-thickened tung oil has been recommended with phenol-formaldehyde resins on the grounds that it exerts a greater solvent action on the resin, has greater anti-gelling power and is cheaper.<sup>148</sup>

#### SUMMARY

The development of phenolic resins in the varnish industry may be indicated by the following stages of progress:

1. After the World War the producers of butyl alcohol turned to nitrocellulose lacquers in search of an outlet for that alcohol. The widespread use of lacquers had been greatly hindered by the lack of adequate solvents for nitrocellulose. Butyl acetate was found to be satisfactory for the purpose and a lacquer industry began which, with the advent of nitrocellulose of reduced viscosity, forged ahead at a rapid pace and acquired a very important position in the coating industry.

2. The solubility in oils which was conferred by natural resins (in particular rosin) on phenolic resins which otherwise would be insoluble gave products which from about 1925 onward met commercial requirements sufficiently to be used quite extensively. One of these products was known as Albertol. Another of somewhat later development was Amberol, which was marketed in various forms. Those phenolic resins which contained rosin were found to be less resistant to weathering influences than some of the natural-resin varnish compositions. The fact that the presence of rosin militated against the life of the coating served, at least in some cases requiring exterior exposure, to diminish the scope of utility of resins of that type. However, nitrocellulose lacquers were so fast-drying and were pushing oil varnishes so hard that varnish producers seized upon modified phenol-formaldehyde resins, despite their defects, because these synthetic resins provided a faster drying effect than was possible to obtain with the varnish gums used up to that time.

3. Hydroxybiphenyl, a by-product in making phenol from chlorobenzene, was found to react with formaldehyde to give an oil-soluble resin (without rosin) which, incorporated with drying oils in the varnish-making procedure, provided varnishes of great resistance to exterior exposure.

4. Concurrently, alkylated phenols were made which likewise possessed the characteristic of dissolving in drying oils. These substituted compounds resembled in their behavior in varnish compositions those of the hydroxybiphenyl type and gave such promising results that their manufacture began and has increased to a considerable scale. The alkylated phenols are made either by treating phenol or one of its homologues with alkylated halide in the presence of aluminum chloride or by causing an olefin to combine directly with the phenol in the presence of sulphuric acid or like condensing agent.<sup>149</sup> The resulting alkyl halide is then

<sup>147</sup> H. Rauch, German P. 402,539, 1922; *J.S.C.I.*, 1925, 44, 17B.

<sup>148</sup> W. Ruckert, *Farben-Ztg.*, 1933, 38, 995; *Brit. Chem. Abs.* B, 1933, 676.

<sup>149</sup> For a review of the various methods of making alkyl phenols see Carleton Ellis, "The Chemistry of Petroleum Derivatives," Chemical Catalog Co., New York, 1934, especially page 565, *et seq.*

resinified by means of formaldehyde. Thus there is further available an oil-varnish resin group of which the important members are of the *p*-tertiary butylphenol type and the corresponding amyl compound.

Resins from hydroxybiphenyl and from the synthesized alkyl phenols have provided varnishes which possess a sufficiently rapid rate of drying to compete successfully with nitrocellulose lacquers. In addition they give a degree of depth and richness of coating not ordinarily obtainable by lacquers without the application of a greater number of coats.

5. Cheaper forms of oil-soluble phenolic resins are provided by those from xylene, it having been found that xylenols produce resins which have good solubility in drying oils and yield durable varnishes. The color of a xylene resin varnish is not always satisfactory for some purposes, since the coating shows a tendency to darken to a slight extent on exposure to light. Other resins which have been used in making oil varnishes are those derived by the action of phenol on acetone and treatment of the resulting compound with an aldehyde. In general, therefore, the development of resins of the phenolic type adequate for use in making oil varnishes calls either for the addition of the solubilizing agent (rosin) to the resin from phenol itself, or for the substitution in the benzene ring of the phenol structure a sufficient number of hydrocarbon or other groups to impart the needed degree of oil-solubility.

The modified phenol-formaldehyde resins undoubtedly have a tendency to accelerate the drying of the various oils used in varnish making. The assertion has been made that the phenolic resins stimulate polymerization of the oil with the result that the coating sets and becomes dust- and tack-free without the necessity of protracted exposure to oxidation in the air. However, since free phenol and cresol act as anti-oxidants, care must be taken that resins prepared for the varnish industry are so free from substances retarding oxidation that the expected acceleration of drying by virtue of the presence of the phenolic resins is not impaired.

## Chapter 20

# Modified Phenol-Formaldehyde Resins

## II. Various Modifying Agents

Fusible phenol-formaldehyde resins possess neither toughness nor elasticity and are notably brittle. Although the infusible resins are hard and strong, they too are somewhat brittle and possess comparatively little elasticity or flexibility. Efforts to supply these properties have been unremitting. If flexibility could be imparted to the product, a non-inflammable substitute for celluloid in many of its applications could be realized. If tough, rubbery, elastic qualities could be developed its application in the rubber field might follow. In the present chapter there are considered various compositions formed by adding to the phenol-aldehyde reaction mixture or to the partially condensed resin certain substances intended to modify the physical qualities of the product. The discussion, however, does not embrace fillers which are considered in the chapters relating to molding compositions (Chapters 65 and 66). Some of the modifying agents such as tung oil probably enter into chemical combination (see Chapter 19) while others are, to a large extent at least, merely inert additions or diluents. The suggestions covering proposed additions to phenol-formaldehyde resins are so numerous that space does not permit detailed descriptions of all of them. Modifiers may be easily obtainable substances, such as glycerol, dibutyl phthalate, starch, dextrin, glue, gelatin, albumin, natural resins and vegetable ivory, as well as a number that are more rare and less easily obtainable, such as intestinal mucin, a serum from cattle blood, alginic acid, cholesterol and the proteins made from corn and beans.

The use of modifiers has spread in the resinous products industry with each succeeding year. As early patents expired the growth of competition narrowed the margin of profit on the older products and a constant search has been continued for modifying agents which would so alter the original properties of the resin that new fields of use would be opened for it. This has brought a great variety of modifiers to light, some of which have attained commercial importance.

### PROTEIN COMPOSITIONS

Phenol is a powerful solvent for proteins such as glue and casein, and early in the history of the development of phenol-formaldehyde resins various suggestions were made for the solution of a protein in phenol and treatment of the mixture with formaldehyde to form thermoplastic substances. Formaldehyde which reacts with both the phenol and the protein, was supposed to harden them both and to yield a product of improved elasticity.

In 1907 Goldsmith<sup>1</sup> used a mixture of gelatin,  $\beta$ -naphthol and formaldehyde for making a molding composition. He termed the formaldehyde an indurating

<sup>1</sup> B. B. Goldsmith, U. S. P. 1,076,417, Oct. 21, 1913; *J.S.C.I.*, 1913, 32, 1164.

agent, as it gave to the composition greater toughness and increased the resistance to the action of water. Also, it minimized the tendency of the composition to stick to the mold. Stockhausen<sup>a</sup> incorporated gelatin with a phenol resin. A modern application of gelatin-modified resins is a cementing material for laminated glass.<sup>c</sup> Fibers have been made antiseptic, waterproof and lustrous by treatment with a mixture of gelatin, boric acid, paraformaldehyde, a phenolic condensation product, alum and camphor.<sup>d</sup>

Berend<sup>e</sup> described the preparation of a modified phenol-formaldehyde resin which contained glue. For example, 150 parts by weight of glue were dissolved in 75 parts each of phenol and glycerol at 70-80°C., and to this was added a solution of 24 parts of shellac in 48 parts of aniline, and finally 30 parts of paraform or 80 parts of a glycerol-formaldehyde mixture containing about 30 parts of formaldehyde was quickly stirred into the composition. This mixture gradually solidified becoming homogeneous and tough, and was molded before it became completely solid. Berend<sup>e</sup> also used casein. Twenty-five parts by weight each of phenol and casein and 2 parts of caustic soda were mixed and heated until the solution became clear and viscous. Then, 50 parts of phenol and 10 parts of trioxymethylene were added, and the mixture was slowly heated to 100°C. to bring about reaction. Further additions of 10 parts and then 5 parts of trioxymethylene were made at intervals. The mixture was thereafter cautiously heated and maintained in a state of gentle ebullition for a period of about 2 hours until a test sample solidified on cooling in the air. Filling materials were added and the composition placed in molds where it was hardened by heating for 6 hours at 100-110°C. and then for a few hours at a slightly higher temperature.<sup>f</sup> Wiechmann<sup>g</sup> prepared modified phenol-formaldehyde resins by reacting paraform with crystallized phenol, and mixing the product with cellulose or albumin. The product was soluble in a mixture of methyl and amyl alcohols, and was useful as a varnish. It was convertible into an insoluble infusible body by the action of heat.

Tarasov<sup>h</sup> added numerous substances to phenol-formaldehyde resins, for the purpose of reducing inherent brittleness. Thus, a mixture of 100 parts by weight phenol, 20 parts egg albumin, 50 parts water, 57 parts of a 37 per cent aqueous solution of sulpho-acids produced from petroleum acid sludge, was heated to 80°C. until the albumin dissolved and about 50 parts of the water had evaporated. Then, the mixture was cooled and 40 parts of formalin solution added. On heating to 80°C. rather violent ebullition occurred on account of the reaction of condensation. Evaporation was resumed, another 50 parts of water removed, the mix cooled to 25°C. and 50 parts of formalin solution introduced. The mixture was now a rather thick liquid. It was poured into a mold and allowed to stand for 12 hours. During this time it became nearly solid. The molds were placed in a bath of water at 75°C. for a half hour, then heated to 90°C. for 1 or 2 hours and finally to 100°C. for the same length of time. The product was an infusible, opaque, yellowish, elastic solid.

Kühl<sup>i</sup> heated cresol and casein with formaldehyde, with or without a small quantity of potassium carbonate, in an autoclave at 3-5 atmospheres pressure. For example, 250 grams of granular casein were soaked in 500 g. of cresol until a uniform mass was obtained. To this was added 400 g. of formaldehyde and the mixture was heated in an autoclave and kept at a pressure of 3 atmospheres for 10 minutes. The product was dissolved in alcohol to form a varnish. According to Nakanishi<sup>j</sup> casein may be dissolved in a concentrated solution of borax and dissolved in 10-20 parts of alcohol. Phenol and formalin were heated with sodium acetate under reflux at about 100°C. for 2 hours and diluted with 20 parts of alcohol. By mixing this with the previously prepared casein solution, a varnish of rich luster was made. A substitute for hard rubber proposed by Parkert is made from mica 35 parts, galalith powder (artificial

horn, made from casein) 85 parts and phenol-formaldehyde resin 26 parts. The resin is put into solution before incorporating it with the fillers.<sup>12</sup>

Hagendorf<sup>13</sup> used the serum from the blood of cattle, in conjunction with formic acid and trioxymethylene or formaldehyde. This mixture was heated with phenol and sodium peroxide until a solid product was obtained. Hydrogen peroxide<sup>14</sup> can be substituted for the sodium peroxide and other albumins may take the place of blood serum. In making knobs, buttons or other articles from proteins such as those of blood, casein or yeast, a protein powder is consolidated by the action of a colloidal solution of protein in dichlorohydrin or phenol and formaldehyde.<sup>14a</sup>

Wiechmann<sup>14b</sup> mixed vegetable ivory with phenol and then treated the mixture with formaldehyde, obtaining a thermoplastic substance which could be transformed into a hard, infusible product. The ground vegetable ivory may be mixed with a liquid or pasty form of a partial condensation product of phenol and formaldehyde, and submitted to further heating until on cooling the material is hard enough to be ground. It can now be molded. In another case, ground vegetable ivory is simply mixed with a pulverized solid partial condensation product of phenol and formaldehyde and the composition is molded under heat and pressure to a hard, infusible condensation product. Wiechmann is of the opinion that reaction takes place between the three essential components and that the vegetable ivory actually is in chemical combination in the molded material.

Frood<sup>14c</sup> describes a floor-covering composition. Fibrous material, before or after treatment with a phenol-formaldehyde condensation product, is disintegrated or shredded in such a manner as to preserve the original length of the fibers, and the product is kneaded to a uniform mass with rubber, casein or animal glue, together with filling material and coloring matter. The fibrous material and rubber respectively may be fireproofed by treatment with solutions of sodium silicate, zinc chloride or antimony trichloride or by chlorination. The composition is rolled into sheets or molded into shape and subsequently vulcanized.

Sato investigated various thermoplastic substances made from vegetable proteins (obtained from corn and beans) combined with phenol and formaldehyde.<sup>14d</sup> The protein was incorporated with the phenol and treated with formaldehyde or hexamethylenetetramine. For example, 100 parts by weight of the protein of corn were mixed with 150 parts of phenol and the mass kneaded to produce a thick glue-like transparent substance of light brown color, and 50 parts by weight of trioxymethylene were introduced. Besides using these compositions in making molded articles Sato also made a lacquer by dissolving them in benzene, petroleum benzine or other solvent. He reported that this lacquer hardened at 30-40°C. to a glossy coating which was resistant to water and common organic solvents. Berlin<sup>15</sup> has suggested that corn-gluten residues be utilized to make molded articles. The moldable mix consisted of 100 parts of starch and fat-free gluten, 8 of phenol, 3 of butanol, 2.5 of glycerol, 3 of hexamethylenetetramine, 2.5 of paraformaldehyde and 5 of water. The mixture is heat-hardened by molding at 150°C. and 3000 pounds pressure for 9 minutes. Phosphatides from soya beans or egg yolk can be treated with solvents for the extraction of oils and then mixed with resinous

plastics. The resulting composition is proposed for the manufacture of phonograph records.<sup>16</sup>

Rubber-like compositions can be made by heating animal glues or gelatins with phenols, and adding formaldehyde under energetic mixing. Various varieties of pitch, resins, gums and the like may be incorporated during the mixing.<sup>17</sup> Another rubber substitute which has been described<sup>18</sup> contains strong glue, 100 parts, salicylic acid, 0.2, gum tragacanth, 25, wood flour, 435, water, 200, glycerol, 125, castor oil, 18, colza oil, 11, fatty soap, 6, suet, 3, resinat treated with formaldehyde, 3, solution of resin (Bakelite in naphtha), 5, potassium dichromate, 3, and potassium alum, 6 parts.

A casein-formaldehyde condensation product is treated with phenol and the composition is powdered, placed in molds and hardened under high pressure at a temperature of 100°C. or more.<sup>19</sup> A material of great hardness and toughness, resistant to oils and relatively high temperatures results. Schroder, Jaroslaw and Levis<sup>20</sup> heated alkaline solutions of albuminous substances (casein, blood, intestinal mucin, oils, plasticizers and fillers of various kinds) with phenol and an aldehyde in the presence of ammonia. Pabst<sup>21</sup> used, for example, 460 g. of casein, wet with 90 g. of water and 90 g. of alcohol, and 40 g. of a mixture of phenol, aldol and rosin, to obtain artificial horn. Carpentier<sup>22</sup> poured a solution of casein in 10 per cent sodium carbonate solution into liquid phenol, dissolved sodium salicylate in the mixture and added formaldehyde. After filtration the mixture was heated under reflux, 80 per cent of the water was removed by distillation *in vacuo* and the residue was heated at 100°C. in molds. Waste from the manufacture of albumin-formaldehyde plastic materials may also be dispersed in phenol and treated at a raised temperature with formaldehyde.<sup>23</sup> When phenol-acetone condensation products are modified with casein, horn-like compositions are obtained.<sup>24</sup> To obtain a shellac substitute, Mellanoff<sup>25</sup> added about 4 parts of a casein solution (100 parts of casein in from 400-800 parts of water containing 16 parts of borax and 10 parts of 26 per cent ammonia) to about 5 parts of a condensation product of phenol and formaldehyde. Aqueous dispersions capable of application as paints, binders or adhesives are obtained by incorporating casein, glue or cyclohexanol with a phenol-formaldehyde resin in presence of an emulsifying agent (e.g., triethanolamine or a saponified sulphonated oil).<sup>26</sup>

Carbonel<sup>27</sup> condensed a mono- or polyhydric phenol with formaldehyde or its polymers in the presence of a salt of alginic acid (an albuminous acid from kelp). The condensation products and the alginic acid were precipitated at the same time by a mineral or organic acid. Hotta and Nakajima<sup>28</sup> employed alginic acid in colloidal form, made by boiling sea weed with dilute caustic soda or sodium carbonate, filtering and acidifying with sulphur dioxide. Fifty parts of the acid thus obtained were dissolved in 100 parts of cresol or phenol mixed with 200 parts of 35 per cent formaldehyde and 25 parts of casein, and heated under pressure to produce

a resin, soluble in alcohol and amyl acetate. Strong and lustrous films were said to be obtained from it. By combining casein with a phenol-formaldehyde condensation a varnish that may be used for coating bobbins is obtained.<sup>29</sup>

Phenol-formaldehyde resin has been used as a binder for leather scrap. The procedure<sup>30</sup> is to hydrolyze the leather under heat and pressure in the presence of phenol, an aldehyde and an alkaline or acid catalyst. The product is plastic and is useful as a heat- or electrical insulator. Phenol-formaldehyde has also been used as a binder for pulverized natural ivory.<sup>31</sup>

### SULPHONATED DERIVATIVES

Sulphonated phenol-formaldehyde condensation products (syntans) have been utilized for the tanning of skins. These products are reported to be superior to earlier reagents containing phenols. It has long been known that skins may be tanned by means of phenols, and the improvement of utilizing the formaldehyde condensation product had its commercial beginnings sometime previous to 1912.<sup>32</sup> Very likely the use of such products in tanning began in 1909 and was kept as a trade secret.<sup>33</sup> Since that time they have become widely used, especially in conjunction with other tanning materials.<sup>34</sup> In a process described by Stiasny,<sup>35</sup> sulphonated phenol or cresol is added to a 40 per cent solution of formaldehyde, and an exothermic reaction ensues, resulting in the formation of a colorless, viscous mass which is soluble in cold water. The solution can be used as a tanning bath. The reaction involved was considered to be:<sup>36</sup>

These sulphonic acids, and certain of their salts, are absorbed by leather in such a way that they cannot be washed out. They render the leather stable and resistant to tear.<sup>37</sup>

Only one mol of formaldehyde is used to every 2 mols of sulphonated phenol, for the solubility of the product diminishes when the amount of formaldehyde is increased.<sup>38</sup> Paraldehyde may be employed in place of formalin solution, and the resin may be sulphonated after the condensation instead of before.<sup>39</sup> Likewise, acetaldehyde reacts with phenols in the presence of catalytic amounts of sulphuric acid, and the resinous product can be sulphonated to form a tanning substance.<sup>40</sup> The product from

acetaldehyde is reported to have better filling properties than the corresponding sytan from formaldehyde, but the yield is lower.<sup>41</sup> Higher phenols obtained from peat tar (fraction boiling 240-280°C.) may be sulphonated and then condensed with formaldehyde in alkaline medium. The tannides produced yield a satisfactory leather at a  $pH$  5.5-4.<sup>42</sup> Replacing phenol by resorcinol or pyrogallol also resulted in conferring good filling properties. The tanning action of the naphthol condensation products is comparatively mild.<sup>43</sup> Resorcinol, condensed with benzaldehyde, yields a clear brown syrup, which is a powerful tanning agent.<sup>44</sup> Similarly, phenol alcohols may be condensed with resorcinol.<sup>45</sup> Likewise, tanning agents have been made by incorporating urea resins with polyvalent phenol-formaldehyde condensation products.<sup>46</sup> Crude acetaldehydedisulphonic acid, made from fuming sulphuric acid and acetylene, condenses with phenols in water solution. The product is a soluble tanning agent.<sup>46a</sup>

The sulphonic acid group may be introduced in various ways other than those above noted (sulphonation of the phenol, or the resin). For instance, naphthalene-sulphonic acid is condensed with hydroxybenzyl alcohol;<sup>47</sup> isopropyl-naphthalene-sulphonic acid, with formaldehyde;<sup>48</sup> p-hydroxy-ter-butylbenzenesulphonic acid, with formaldehyde;<sup>49</sup> benzylnaphthalenesulphonic acid, with the phenol-formaldehyde condensation product;<sup>50</sup> alkyl sulphonyl chloride and phenol, with formaldehyde.<sup>51</sup> Hydrogenated syntans can be made by hydrogenating the initial phenol-aldehyde condensation product and introducing the sulphonic group by means of chlorosulphonic acid.<sup>52</sup> Tarasov<sup>53</sup> was able to modify the degree of hardness, elasticity, chemical resistance, solubility and fusibility of the phenol-formaldehyde condensation products by incorporating Russian turpentine oil, sulphonated castor oil (or sunflower seed oil) and sulphonated petroleum. Evidently his products were not intended for use as tanning agents, but were more especially to be used as moldable resins or compositions which could be machined. As an example, a mixture of 50 g. sulphonated sunflower-seed oil, 100 g. phenol, 10 g. sulphonated naphtha and 50 g. formaldehyde is heated. At 50-55°C., an exothermic reaction begins, causing violent ebullition. The mixture becomes viscous, and is poured into molds. Upon further heating it is transformed into a solid free from cracks and bubbles.

Chestakoff,<sup>54</sup> as a means of improving the quality of condensation products from cresol and formaldehyde, proposed the addition of an organic sulphonic acid of high molecular weight and high dispersive power. He employed octahydro-anthracenesulphonic acid, isopropyl-naphthalenesulphonic acid and the acids obtained by sulphonating mineral oils. Polymerized products obtained by the distillation of neutralized sulphonated mineral oil can be incorporated in phenol-formaldehyde resins by heating a mixture of the polymers with phenol and

formaldehyde for 1-6 hours at a temperature of about 100°C., in the presence of a small amount of sulphuric acid.<sup>55</sup> When colophony is heated with phenol and sulphuric acid, clear solutions are formed. That these solutions have good tanning properties is indicated by the fact that they give heavy precipitates with gelatin.<sup>56</sup>

For the preparation of syntans, it occasionally happens that the condensation of phenol with formaldehyde is carried out in the presence of inorganic sulphites. Thus, sulphonated phenol is condensed with formaldehyde in the presence of sulphite, after which oxalic acid is added.<sup>57</sup> Alternatively,<sup>58</sup> the phenol-formaldehyde condensation product can be made first, and then treated with sodium sulphite. The water-soluble products obtained from phenols (phenol, m-cresol, p-chlorophenol) by condensation with formaldehyde and a sulphite are heated with sulphur and water in the presence of alkali, and tanning agents are formed.<sup>59</sup>

The condensation of sulphonated phenol with formaldehyde may be performed in various non-aqueous solvents, acetone, alcohols, ethyl acetate, acetic anhydride and a number of others.<sup>60</sup> In fact, if the tanning materials made in this way are to be used in alcoholic solution, as in the case of skins dehydrated with alcohol,<sup>61</sup> it is not necessary to sulphonate the phenol, or the methylenediphenol condensation product. It is possible to use such a condensing agent as sodium phenolate instead of sulphuric acid. Acetone may be employed before the introduction of the formaldehyde, and thus it also enters into combination with the phenol.<sup>62</sup> The product is made soluble by sulphonation.

In preparing the sulphonated methylenediphenols, acid condensing agents (hydrochloric and sulphuric acids) are usually employed, but many alkaline agents have also been used. Thus, cresol is condensed with formaldehyde in the presence of a small amount of sodium bicarbonate<sup>63</sup> or ammonia,<sup>64</sup> the reaction being carried out in an autoclave at about 110°C. Similarly, sulphonated phenol or cresol condenses with formaldehyde in the presence of ammonia or amines.<sup>65</sup>

The introduction of amido groups into sulphonated phenol-formaldehyde resins evidently improves their tanning properties. Urea, thiourea, polysulphides, calcium thiocyanate and ammonium thiocyanate<sup>66</sup> have been used in this manner. Cyclohexylamine and ammonia may also be employed.<sup>67</sup>

Preliminary condensation of phenol with sulphonated ricinoleic acid, followed by condensation with formaldehyde, has been described as a method for producing tanning agents.<sup>68</sup> An aromatic hydroxy acid, salicylic acid, had been used

previously in a similar way.<sup>66</sup> It is possible to carry out the condensation between the phenol, formaldehyde and ricinoleic acid, and subsequently sulphonate the resin,<sup>70</sup> or to use oleic acid in place of ricinoleic.<sup>71</sup>

The sulphonation product<sup>72</sup> of a mixture of phenol and a fat, oil, wax or resin can be condensed with an aldehyde to resinous products for use as dispersing and tanning agents. Phenol and wool fat after sulphonation may be condensed with formaldehyde, or cresol and castor oil after sulphonation may be condensed with acetaldehyde.

Other variations from the simple sulphonated methylenediphenols are attained through the introduction of alkyl or substituted alkyl groups, often by means of a condensation reaction in which hydrogen chloride is eliminated. Halogenated phenols may be employed in preparing the initial condensation product,<sup>73</sup> or the ketone or aldehyde to be condensed with the phenol may be chlorinated,<sup>74</sup> as in the case of chloroethyl methyl ketone, chloroacetone, and chloroacetaldehyde. The sulphonated resin from chloroacetone and phenol reacts with waxes, oils and tetrahydronaphthalene, to give products which are still water-soluble.<sup>75</sup> Chlorinated lignite degradation products may be incorporated with phenol-formaldehyde resins, to produce tanning agents.<sup>76</sup> Inorganic catalysts are sometimes of value in assisting the condensation of chlorine compounds with the phenol-formaldehyde product. Thus, p-sulphonylbenzylchloride is condensed in the presence of zinc chloride, aluminum chloride or sodium hydroxide.<sup>77</sup> Instead of the sulphonyl chloride, a mixture of aromatic hydroxy sulphonic acid and sulphur chloride or phosphorus oxychloride may be employed.<sup>78</sup>

Synthetic tanning agents are improved by the addition of fluosilicates,<sup>79</sup> which keep the syntan free from mineral acid. For example, cresolsulphonic acid is condensed with formaldehyde, and the product is neutralized with sodium carbonate. Then, dry sodium fluosilicate is added until the amount present is one-third of the weight of the product.

Still another modification of the sulphonated phenol-formaldehyde resins is the combination of the initial condensation product with sugars or cellulose derivatives, especially waste sulphite cellulose liquor.<sup>80</sup> Grape sugar, fruit sugar, levulinic acid and salicylaldehyde have also been used.<sup>81</sup> A specific procedure is: 100 parts of dextrose are dissolved in 350 parts of sulphuric acid, and 150 parts of phenol are added at a temperature of 40°C. while the mixture is kept agitated. The resulting product is neutralized with caustic soda.<sup>82</sup> The affinity which exists between cellulose derivatives and compositions of the syntan type is made use of by employing these com-

positions in dispersing insoluble dyes for acetate rayon.<sup>55</sup> The staining of esterified-cellulose threads is diminished by adding to the dyebath condensation products of aromatic phenols with sulphuric acid and formaldehyde.<sup>56</sup>

The sulphonated methylenediphenols have the power of colloiddally retaining gases, and have been used as "foaming agents."<sup>57</sup> Another group of sulphonated phenol-formaldehyde resins is constituted by the products which result from treating the initial resin with substituted sulphonyl chlorides. These resins are characterized by a comparatively light color, which is fairly stable in the presence of light and air. Melamid<sup>58</sup> obtained resin-like substances by condensing a phenol and formaldehyde to produce a phenol-alcohol, and subsequently esterifying in caustic soda solution with a benzol solution of an aromatic sulphonyl chloride. For example, 100 kg. of cresol-alcohol (made from commercial cresol and formaldehyde) are dissolved in 300 kg. of 10 per cent caustic soda solution and the solution stirred for several hours at a temperature not exceeding 30°C. with 137 kg. of a mixture of o- and p-toluene sulphonyl chloride or one or other of these isomers in 500 kg. of benzene. The benzene is washed free from alkali, dried, and the resin recovered by evaporation. The initial phenol-alcohol may be made in the presence of the aromatic sulphonyl chloride and the product further treated with sulphonyl chloride. Phosgene or an organic acid anhydride, e.g., acetic anhydride, may be used instead of the sulphonyl chlorides.

Melamid's observations, according to Jacobsohn,<sup>59</sup> resulted in the development of a light-yellow, odorless resin of notable stability of color. A soluble resin of low melting point first is prepared from cresol and formalin, using a small proportion of hydrochloric acid as a catalyst. The resin is esterified with p-toluenesulphonyl chloride, or it may be acetylated. The protection given the hydroxyl groups by this treatment improves the color stability of the resin. Resins treated with p-toluenesulphonyl chloride harden rapidly in the cold.<sup>60</sup>

Phenols treated with sodium bisulphate and thiosulphate can be converted, according to Pfautsch,<sup>61</sup> into synthetic resins which do not discolor on keeping.

Bucherer<sup>62</sup> recommended that the free phenolic groups of the resinous condensation products from phenols and formaldehyde be substituted by organic radicals (alkyl, aralkyl or acyl groups) to render the products insoluble in alkali, and to modify their solubility in organic solvents. p-Toluenesulphonic, benzoic, salicylic, cinnamic, acetic, valeric and bromovaleric esters of the resins, their benzyl ethers and mixed ether-esters are soluble in various organic solvents. Their carbonic acid esters, which are practically insoluble and have high melting points, may be prepared *in situ* upon textiles, wood, paper, by treating the material impregnated with alkaline solutions of the resins with carbonyl chloride.

In the manufacture of colorless<sup>63</sup> or very light-colored insoluble condensation products from phenols and aldehydes, the color-forming constituents of the readily condensable intermediate products are removed by extraction with such agents as ether.

## CHLORINATED COMPOUNDS AS SOFTENING AGENTS

Just as formaldehyde or hexamethylenetetramine increases the rate of conversion of fusible, soluble, soft resin into infusible insoluble hardened resin, so also many substances, called softening agents, tend to prevent the progress of this conversion or to soften the product, once the conversion has taken place. Monochloronaphthalene is especially useful for this purpose. It is liquid at room temperature, and remains in the hardened composition, evidently dissolved in the solid resin.<sup>92</sup> Instead of monochloronaphthalene, other chlorinated compounds, tetra- or pentachlorophenol, may be employed.<sup>93</sup>

A resin was made by Mannesmann<sup>91</sup> from phenols, especially m-cresol, and aldehydes in the presence of chlorinated hydrocarbons, and without acid or alkaline catalysts.

Cresol-formaldehyde resin is soluble in monochloronaphthalene in all proportions. Phenol-formaldehyde resin and monochloronaphthalene, however, are not mutually soluble in all proportions. Monochloronaphthalene is soluble in an equal amount of phenol resin when heated, but larger amounts of monochloronaphthalene will not remain in solution.

Enamel or lacquer compositions which are to be hardened by subsequent heat treatment may be made by compounding cresol-resin and hexamethylenetetramine with free cresol and a fluid chloronaphthalene. The proportions of the latter ingredient may vary within wide limits, as much as 2 parts of the monochloro compounds to 1 part of the cresol resin being used, the amount depending on the fluidity and character desired in the varnish or lacquer. Free cresol may also be added and if employed in large percentages, the amount of hexa is proportionally increased.

Free cresol is used, if monochloronaphthalene is the solvent, for thinning the composition and also because it yields a better impregnating varnish, for coils and the like. In such a composition, the hardening agent (hexamethylenetetramine or trioxymethylene or some other solid anhydrous polymer of formaldehyde) is added in the proportion of 3 or 4 per cent of the weight of the cresol resin plus 20-25 per cent of the weight of the free cresol used. Also, solid chloronaphthalenes or chlorophenols may be added to the solution since they have the property of reducing the shrinkage of the varnish film during and after hardening, the coefficient of expansion of the cresolic compositions being greater than that of resins made from phenol.<sup>96</sup>

Aylsworth utilized a combination of chloronaphthalene and phenylphthalimide, in these proportions: 100 parts phenol resin, 10-30 parts cresol or monochloronaphthalene, 20-70 parts phenylphthalimide, 0-100 parts filler.<sup>95</sup> Baekeland employed a chlorinated hydrocarbon with anhydroformaldehyde-aniline. Sym.-dichloroethane, tetrachloroethane and monochloronaphthalene were the chlorine compounds specified.<sup>97</sup> Likewise, Petrov<sup>98</sup> employed the chlorinated derivatives of ethane and ethylene, combining these in the presence of either acid or alkaline catalysts, with the semi-condensed products of phenol-formaldehyde.

<sup>98</sup> G. S. Petrov, Russian P. 4333, 1923; *Chem. Abs.*, 1929, 23, 1227.

Polychlorinated naphthalene also finds application in conjunction with phenol-formaldehyde resins. Benzoic acid, which may also be used for controlling the polymerization of the intermediate resins, is not superior to polychlorinated naphthalene or many other cheap waxy materials.<sup>99</sup> A mixture of 14 parts Halowax (chlorinated naphthalene), 16 parts 45 per cent phenol-formaldehyde resin solution, 2 parts aluminum stearate and 13 parts maize oil is applied to a fabric backing to make a stencil paper.<sup>100</sup> The resin is heat-hardened on the sheet. Sealing compositions can be made by dissolving a phenolic resinoid in wax-like halogenated naphthalene.<sup>101</sup>

Guntzel proposed a method for producing a viscous phenol condensation product containing p-dichlorobenzene. One l. of phenol is mixed with 600 cc. 40 per cent formaldehyde solution. About 80 g. p-dichlorobenzene is introduced, and the mixture is heated to melt the dichlorobenzene, and, under vigorous stirring, to form a homogeneous mixture. A mixed salt consisting of 60 parts common salt, 10 parts ammonium chloride and 30 parts hexamethylenetetramine is then added in quantity corresponding to one per cent of the weight of phenol used. After the batch has been heated for a time, it is washed several times with cold water. The liquid syrupy product which remains may be hardened by heat.<sup>102</sup>

Weith<sup>103</sup> described the preparation of a resin by the use of a rather large amount of hexamethylenetetramine in the initial stage together with a plasticizing agent. Equimolar portions of methylene and phenol would require 6 mols of phenol to 1 of hexamethylenetetramine, but Weith employed a proportion of 3 to 1. In his procedure, 175-190 g. phenol, 25-10 g. o-cresol, 86 g. hexamethylenetetramine and 65 g. monochloronaphthalene are mixed together. To this is added 2 cc. butyl stearate and 1.5 cc. castor oil. The mixture is heated in an open vessel to 135°C., at which temperature an exothermic reaction begins. When the reaction has become slower, and the temperature has fallen to 125°C., the mass is poured into shallow molds, in which it is hardened at 120°C. under 80 pounds pressure.

#### AMINES AS SOFTENING AGENTS

Bakeland used aniline as a solvent or flux for infusible phenol-formaldehyde resins.<sup>104</sup> Aniline has a pronounced softening action on these resins, especially at high temperatures, and permits infusible particles or fragments to be welded together into compact, coherent masses under heat and pressure. A variety of amines, including xylidines, toluidines, benzidine and diphenylamine, has been proposed<sup>104a</sup> for use with phenol-hexamethylenetetramine resins. According to Hubacher,<sup>106</sup> the resin made from acetaldehyde and phenol modified with aniline may be employed as an antioxidant in vulcanized rubber. The introduction of aniline into a phenol-formaldehyde resin may be carried out<sup>106</sup> by first condensing the amine with formaldehyde in the presence of water at room temperature, and then mixing the product with an alkaline solution of phenol-aldehyde resin in a water-miscible solvent (alcohol). A composite easily moldable product precipitates.

The condensation product of aniline and formaldehyde is anhydroformaldehydeaniline,  $(\text{CH}_2\text{NC}_6\text{H}_5)_3$ , and this may be used in place of aniline as a softening agent. Goldsmith obtained a compound soluble in acetone and having the physical characteristics of a resin by heating together a phenol or a fusible phenol-

formaldehyde resin and anhydroformaldehydeaniline.<sup>107</sup> It might be expected that the methylene groups which it contains would cause a hardening action, and, in fact, Baekeland<sup>108</sup> found that the use of up to 110-130 parts of anhydroformaldehydeaniline to 100 parts of fusible resin is accompanied by increase in the hardness of the final product, while still higher proportions show increased plasticity, especially at high temperatures. This reagent, in contrast with hexamethylenetetramine, liberates no readily volatile by-product in the hardening of a resin from a fusible to an infusible state. Baekeland incorporated the anhydroformaldehydeaniline through the use of a hydrocarbon solvent.

Bender<sup>109</sup> prepared resins by condensing phenol with anhydroformaldehydeaniline, following up with hexamethylenetetramine and fillers. He subscribed<sup>110</sup> to the theory that when aniline is used as a condensing agent<sup>111</sup> in the preparation of phenol-formaldehyde resins, anhydroformaldehydeaniline is first formed, and that this body reacts with a portion of the phenol, setting free aniline, thus providing for a recurrence of the cycle. He therefore considers reactions involving anhydroformaldehydeaniline to be substantially similar to those occurring when aniline and formaldehyde are introduced separately.

Thus, 250 parts of aniline are added to a mixture of 500 parts phenol, 800 parts 37.5 per cent formaldehyde and 5 parts hexamethylenetetramine. At first, considerable heat is evolved, and then the reaction requires heating to keep the mixture at 160°C. until free from water. Upon sufficient application of heat a hard, infusible body is formed. Products of this type have excellent electrical insulating properties. Lume may be used instead of hexamethylenetetramine in the initial condensation, and aniline may be expelled from the condensation product by distillation under reduced pressure.<sup>112</sup>

Resins which are thermohardening, light-resistant and soluble in common low-boiling solvents are formed when formaldehyde is caused to react with phenol, urea and p-toluenesulphonamide.<sup>113</sup> In a similar procedure, Bender<sup>114</sup> caused phenol to react with formaldehyde, combining the excess formaldehyde with urea, thiourea or p-toluenesulphonamide. After acidification, the mass was dissolved in alcohol to form a varnish.

Modification of phenol-formaldehyde resins can be brought about by the use of fatty acids and amines. For example, 56.8 parts by weight of stearic acid and 18.6 parts of aniline are heated at 170-200°C., allowing the water formed to escape. After 1 hour, 19 parts of furfural are added, and the whole mass is heated to about 200°C for approximately 0.5 hour. On cooling, it solidifies to a dark brown waxy solid which may be added to phenolic condensation products to promote ease of molding.<sup>115</sup>

According to Groff<sup>116</sup> it has been commonly considered that molded articles containing considerable proportions of nitrogen are apt to be deficient in electrical insulating quality, but this rule does not apply if the molded product is substantially dehydrated and sufficiently impervious to water. The addition of rosin or carnauba wax and mica to a phenol-hexamethylenetetramine resin increases the water-repelling character, and also results in retarding the conversion of the fusible resin to the infusible form.

Assisting-agents for use in dyeing may be made by causing organic nitrogen bases (e.g., aniline, diethylamine, pyridine) to react with the condensation product

prepared by adding phenol to a hydrochloric acid-formaldehyde solution.<sup>117</sup> A solution for coating or impregnating paper can be made by modifying a phenol resin with natural resins. The procedure<sup>118</sup> is to react formaldehyde with a mixture of  $\beta$ -naphthol and phenol or resorcinol, and to add shellac, rosin, sandarac and kerosene or benzene. Sodium sulphite is now introduced, and the mixture is warmed to 80-85°C. After cooling, milk of lime solution, or an aqueous solution of coloring substances, is added. The impregnation takes place at 180-200°C. under pressure.

#### RESINS MODIFIED BY WAXES, PITCH, GUMS, OR TARs

Tar oils, tars and pitches may be blended with reactive phenol-formaldehyde resins by first reacting the tarry matter with sulphur chloride or thionyl chloride, and then melting the factice with the phenol-formaldehyde condensation product.<sup>119</sup> Sulphonated resins, subsequently treated with ammonia or an organic base, will combine with various gums and waxes.<sup>120</sup> Also, sulphonated fats and waxes (wool fat, carnauba, spermaceti) can be treated with formaldehyde, and then condensed with phenol.<sup>121</sup> Saponifiable waxes such as montan wax, beeswax or carnauba wax may be united with phenol-formaldehyde resins by esterifying the carboxyl groups of the waxy acids with the hydroxyl groups of the resin. The products are thermoplastic, but they do not melt. If formaldehyde is added during the esterification, the resulting resin is hard and not thermoplastic.<sup>122</sup>

Nash used stearin pitch as a modifier<sup>123</sup> by dissolving it in benzene. After adding 5 parts of the solvent to 15 parts of the pitch, the solution is mixed with approximately 142 parts by weight of phenolic condensation product, and the mixture is kneaded with 500 parts of asbestos or other filler to yield a material which can be molded and cured by heat-treatment. Because of the plasticity imparted by the stearin pitch, the resin may be worked in a more advanced stage of condensation. Novotny<sup>124</sup> proposed to modify synthetic resins by adding natural resins of plant origin containing phenolic tannols (red and yellow gum accroides, gum benzoin and dragon's blood). As an example, 50 parts by weight of U. S. P. phenol, 42.5 parts of furfural and 35 parts of gum accroides are mixed together, and heated to dissolve the gum. The mixture is strained to remove impurities, and 0.75 parts of potassium carbonate are added to the clear product. After refluxing or preferably distilling through a separator (see Chapter 17) for 2.5 hours, an end temperature of 200°C. is reached and a hard grindable resin melting at approximately 200°C. is produced.

A plasticized composition for coating and lining pipes that are subjected to low temperatures is prepared by incorporating a mixture of pitch and asphalt with a phenol-formaldehyde condensation product at 230°C.<sup>125</sup> A non-inflammable composition to be utilized as a polish for wood or leather contains chloronaphthalene, a phenol or cresol resin and carbon tetrachloride.<sup>126</sup> Waxy materials were also used by Pungs and Stade,<sup>127</sup> who condensed phenol and formaldehyde with an alkaline condensing agent in an emulsion of wax such as carnauba, montan or beeswax. The

waxes may be replaced by the wax acids or their salts. Hónel<sup>128</sup> used other phenolic resins for the same purpose. In the preparation of these resins p-cresol, p-amyl phenol or p-butyl phenol replaced phenol.

Plastic masses, stated to be useful as insulating material, were obtained by Plauson<sup>129</sup> by modifying phenol-aldehyde resins with lignite-extracts. Powdered lignite is treated with caustic soda, the extract filtered and treated with a concentrated mineral acid and evaporated to dryness. The residue is added to a mixture of a ketone or aldehyde (for example, acetone or formaldehyde), a phenol (e.g., resorcinol) and concentrated hydrochloric acid and the whole is heated under pressure at 150-200°C. A homogeneous black mass results.

### THE USE OF CHLOROACETIC ACID

It is evident that, if a carboxyl group is present in a synthetic resin the possibility of esterification with hydroxyl groups is introduced. In this way the properties of the resin can be considerably altered. Accordingly, when partly condensed aldehyde-phenol products are heated with chloroacetic acid or  $\beta$ -bromopropionic acid in the presence of alkali, fusible carboxylated resins which are soluble in alkali are obtained.<sup>130</sup> The haloaliphatic acid may be introduced after the resin has been prepared, in which case less than 1 mol of halogen fatty acid is used.<sup>141</sup> Dichloroacetic acid, or chloromalonic acid may be used in like manner.<sup>132</sup>

The ammonium salt (or substituted ammonium salt) of carboxylated phenol-formaldehyde resin has valuable properties. It is soluble in water and various kinds of fillers may be added to its aqueous solution. With paper pulp it forms a resin which can be used in the manufacture of molded articles. With glycol, glycerol, mannitol or polyvinyl alcohol (obtained by the saponification of polyvinyl acetate),<sup>133</sup> it forms an insoluble, infusible body.<sup>134</sup>

It is not essential to use the ammonium salt when the carboxylated resin is to be reacted with polyhydric alcohols. The carboxy derivative may be precipitated by acid and then esterified with glycol or glycerol. The product is insoluble and infusible, but remains elastic when heated to 150-170°C.<sup>135</sup> A phenoxy aliphatic acid may be substituted for chloroacetic.<sup>136</sup>

A further modification of the polyhydric-alcohol-esterified-carboxylated phenol-formaldehyde resin is attained through the addition of linseed oil fatty acids or ricinoleic acid.<sup>137</sup> The product is a water-resistant binding agent for abrasants.

### POLYHYDRIC ALCOHOLS

The addition of glycerol as a softening or plasticizing agent to phenol-aldehyde resins has received much attention. Purified phenol-aldehyde resins (prepared by washing the crude condensates with hot water, dilute acid and cold water) are

believed to combine with the polyhydric alcohols,<sup>138</sup> the amount of combination being probably dependent on the amount of free phenol or aldehyde present in the resin. Simple plasticization is not accompanied by chemical combination.

In the presence of catalysts (sulphuric and sulphurous acids and salts) and upon prolonged refluxing, glycerol resinifies to form a dark-brown, viscous, water-soluble product. On further heating, loss of water occurs, and the resin becomes infusible. The initial resin corresponds to the formula  $(C_7H_5O_2)_n$ , and apparently contains 2 hydroxyl groups. It is suggested as an adjuvant to bakelite-type materials.<sup>139</sup> Instead of resinified glycerol, a resinous mixture<sup>140</sup> containing a glycerol-polycarboxylic condensation product and natural resin may be used, sufficient glycerol being provided to esterify the acid groups of the natural resin. A similar procedure is to condense the phenol-formaldehyde resin with a carboxylic acid (oxalic, succinic, lactic), introducing the polyhydric alcohol (glycerol, glycol, polyglycerols) during the last stages of the condensation.<sup>141</sup> Still another variation is to heat the phenol-formaldehyde resin with a fatty acid glyceride (castor oil, boiled linseed oil) in the presence of a monohydric alcohol, which can to a certain extent liberate glycerol from the glyceryl ester.<sup>142</sup> If the initial synthetic resin is so constituted that it contains a carboxyl group, it can be modified by heating first with a fatty acid or fatty acid ester of low volatility, and subsequently with a polyhydric alcohol, preferably in a vacuum at 150-200°C.<sup>143</sup>

Beckmann and Dehn have been able to modify the phenol-furfural resins by means of a wide variety of agents, including polyhydric alcohols.<sup>144</sup> Luft<sup>145</sup> and Lebach<sup>146</sup> suggested the use of substances such as camphor, rubber and glycerol to prevent hardening of phenol-aldehyde resins. A similar use of glycerol was proposed by Grognot.<sup>147</sup> Labbé<sup>148</sup> added acetone or glycerol to produce transparent phenol resins.

Mehta<sup>149</sup> heated phenols or cresols with an equimolecular proportion of formaldehyde in the presence of potassium or sodium hydroxide and a small proportion of ammonia and glycerol *in vacuo* at 100-125°C. for 6 hours. Typical proportions are 65 parts of phenol, a corresponding equimolecular quantity of formaldehyde, 0.1063 part of potassium hydroxide, 1 part of ammonia and from 2-10 per cent of the weight of the mixture of glycerol. The only liquid thus obtained is hardened by heating in a mold *in vacuo* for 1 hour and then at 0.5 atmosphere pressure for 2 hours at 150°C. These resins are stated to be specially resistant to decolorizing by sunlight. The function of the glycerol appears to be to take care of the small amounts of water that are not removed by the vacuum-hardening. If less than 1 per cent of glycerol is used the product is opaque, with more than 10 per cent it is hygroscopic. Without ammonia, the resin is clear and with ammonia it resembles amber.

Schmidt<sup>150</sup> added polyhydric alcohols or their esters to retard polymerization and to serve as clarifying agents. Glycol, glycerol, sorbitol or their esters such as

diacetin, glyceryl monopropionate, ether alcohols, acetanilide or mixtures of these substances may also be used. Voss<sup>151</sup> employed polyhydric alcohols such as glycol, glycerol, mannitol or polyvinyl alcohol to modify phenol-formaldehyde resins previously treated with chloroacetic acid. An alkaline solution of sucrose was added to soluble phenol-formaldehyde condensation products by Loetscher<sup>152</sup> in order to produce a varnish resin. Halogenated polyhydric aliphatic alcohols<sup>153</sup> (chlorohydrin,  $\alpha$ ,  $\alpha'$ -dichlorohydrin) have been suggested for treating the condensation product of technical cresol and formaldehyde. Small additions of sodium glycerate were proposed by Heinemann<sup>154</sup> to improve the quality of phenol-aldehyde resins. Berend<sup>155</sup> used glue with the glycerol. Drummond<sup>156</sup> added glycerol acidified with hydrochloric acid to an initial phenol-aldehyde condensate and recommended hypophosphorous acid as a bleaching agent.

Hardenable resins insoluble in water can be made by reacting phenol alcohols with chlorohydrins. Thus, diphenylolpropanetetra-carbinol is dissolved in alcoholic sodium hydroxide and boiled with ethylenechlorohydrin.<sup>157</sup> The viscous product which is obtained has the following structure:

It is convertible into an insoluble infusible resin by heat. When polyhalohydrins are used, the products may contain halogen, and may be further condensed with phenols or organic acids. In this way, soluble resins, useful as ingredients of varnish, are made.<sup>158</sup> A resin may be produced by causing ethylene dichloride or amylene dichlorides to react with a compound containing two or more hydroxyl groups, e.g., resorcinol. The reaction is continued until a tenacious product which does not flow at ordinary temperature is obtained.<sup>159</sup>

To produce phenol-aldehyde resins of ivory-like appearance, Kulas and Pauling<sup>160</sup> heated phenol and formaldehyde in the presence of an acid condensing agent, added an alkaline condensing agent in excess, and then a plasticizer such as amyl alcohol with camphor oil and glycerol. The mixture was boiled to dehydrate it, glacial acetic acid was added, and the resin was hardened by heating at atmospheric pressure. By way of illustration, 0.2 kg. of phenol and 20 g. of water, 0.2 kg. of 30 per cent formaldehyde solution, 5 g. of hydrochloric acid (sp.gr. 1.15) or 5 g. of oxalic acid were boiled together until a resin formed. After this, 0.8 kg. of phenol and 80 g. of water, 2.8 kg. of 30 per cent formaldehyde solution and 0.1 kg. of sodium carbonate were added and the mixture was again boiled until a new formation of resin was completed. After settling, the supernatant liquor was drawn off and the resin thoroughly washed, at first with acidulated water and then with pure water. A mixture of 25 g. of amyl alcohol, 15 g. of camphor oil and 10 g. of glycerol was then added, followed by glacial acetic acid and the resin was hardened by heating at about 110°C. introduced 3 per cent of a mixture containing 90 parts of acetic acid, 7 parts of camphor, 2 parts of glycerol and 1 part of hydrochloric acid into the phenol-formaldehyde product to make the resin more transparent.

Fayolle<sup>150</sup> obtained by the following procedure a product useful in rendering fabrics waterproof and as an electrical insulator. Two parts by weight of sulphuric acid (60°Be.) are added to 1 part of glycerol, the mixture is allowed to cool, and from 1 to 1.5 parts of formalin (40 per cent) are then added. The mixture is again cooled, and, after adding 5 parts of water, 1.25 parts of phenol are slowly poured into it with constant stirring and external cooling. The mixture is then left at rest for 20 hours, when the product will be found as a layer on the surface of the liquid. Gradual hardening occurs on exposure to the air. The formaldehyde may be replaced by methylal and the phenol by cresol. Another formula is: glycerol 1 part, concentrated sulphuric acid 2.2 to 3.3 parts, 40 per cent formaldehyde 1 part, water 0.7-1 part, phenol 2-3 parts. When the amount of phenol is limited to 1 part, the product is obtained by vigorous stirring with 10-20 per cent by weight of concentrated sulphuric acid, but if more phenol is used it may be necessary to heat the mixture on a water bath, and incorporate 10-20 per cent of flowers of sulphur, or to add casein or carbohydrates for otherwise a pitchy substance is formed. When only 0.7 part of phenol is employed, the product is a wax-like solid, soluble in alcohol, and may be utilized in the preparation of varnishes.

#### ETHERS AND ESTERS AS MODIFIERS

Petrov<sup>151</sup> effected the condensation of phenols and formaldehyde in the presence of hydrochloric, phosphoric or benzenesulphonic acids, together with acetic esters of glycerol or cellulose. A mixture of the ingredients, including, however, only part of the aqueous formaldehyde solution, was boiled and after separation of water the remainder of the formaldehyde was introduced. The product was molded and thermally hardened. Bruhat<sup>152</sup> used glyceryl esters such as glyceryl mono-oxalate. For example, the condensation product of phenol with hexamethylenetetramine was mixed with 10 per cent of glyceryl mono-oxalate to yield a material which was partially hardened by storage at 15°C. for several hours before it was molded into shape, and the hardening process completed by heating at 80-100°C. It was molded immediately and hardened subsequently by heating in air. Solutions in alcohol or acetone could be used as a varnish.

Conover<sup>153</sup> heated a fusible resin such as one from phenol and formaldehyde or from glycerol and phthalic acid with diethyl phthalate to produce a homogeneous product which becomes relatively infusible under further heat treatment and is suitable for waterproofing or for the manufacture of molded articles. Butyl palmitate, amyl stearate, esters from aliphatic polybasic acids and polyhydric alcohols,<sup>154</sup> glyceryl monopropionate or monobutyrate<sup>155</sup> all are among the esters that have been proposed. Similarly, polyalkylene glycol aryl ethers or esters such as polyethylene glycol cresyl ether or acetate<sup>156</sup> may be used. For instance, 10 parts of soluble phenol-formaldehyde, made by the use of ammonia as a condensing agent, are heated with 3 parts polyethyleneglycol cresyl ether, prepared by reacting technical cresol with 3 mols of ethylene oxide. The heating is continued for 25 hours at 95-135°C. The product is hard and clear, and can be worked with tools.

Jäger<sup>166</sup> added esters of aromatic hydroxy compounds and inorganic non-volatile acids (the sulphuric or phosphoric acid esters of phenol, naphthol or amyl alcohol) or compounds such as the  $\beta$ -naphthol ester of isopropyl  $\beta$ -naphthalenesulphonic acid to phenol-formaldehyde resins to obtain dull, clouded or opaque white products. The esters can be added when the distillation for the removal of water is almost completed.

Kline<sup>170</sup> allowed about 100 parts of phenol to react with about 200 parts of 40 per cent formaldehyde in the presence of an acid catalyst (oxalic acid) and about 70 parts of diethyl phthalate. After the removal of water, the reaction product is mixed with filling materials (lithopone) in glass, porcelain, enamel-lined or chromium-plated apparatus to obtain substantially colorless resinoids usable in white molding compositions. The surfaces in contact with the resinoid should be free from metals subject to attack by dilute acids. A volatile solvent may be added during the incorporation of filling materials.

Sutherland<sup>171</sup> varied the flexibility of condensation products formed from hydroxyaromatic alcohols and cyclic ethers of polyhydric alcohols by changing the ratio of the quantities used. As a general rule an increase in the amount of the ether increases the flexibility of the final product.

Phenol aldehyde resins may be made somewhat elastic by adding phenyl esters<sup>172</sup> as, for instance, phenyl benzoate or phenyl stearate.<sup>173</sup> Cyclohexanyl esters dissolve stage B resins, and the solutions, when mixed with fillers, are heat-hardenable.<sup>174</sup>

The glycerol ester<sup>175</sup> of lactic acid as a modifier gives clearer products. It is added to the condensation product of phenol and an excess of formaldehyde in the presence of at least 3 per cent of caustic soda. Likewise, the alkyl esters of citric acid have been employed.<sup>176</sup>

Butyl acetate has been used as a medium by means of which iodoform can be incorporated into soluble phenol-formaldehyde resins. In this manner light-sensitive coatings were prepared. In the development process, the resin which has been unacted upon by light remains soluble and can be washed away, and an insoluble product remains where the light was incident upon the film.<sup>177</sup>

The modification of phenolic resins by phenyl derivatives (anisole, acetophenone or methyl benzoate) together with hexamethylenetetramine or hydrobenzamide has been proposed. The constituents should be used in quantities such that the final resin contains approximately equivalent molecular proportions of phenyl and methylene groups. During the reaction ammonia is evolved, and the mixture gradually becomes viscous and solidifies on cooling. At this stage the compound is soluble in alcohol and may be used as a varnish. The reaction may be carried to this stage by boiling a solution of the mixture in alcohol or other non-aqueous solvent. Further heating of the compound produces an infusible, insoluble substance, which may be used as a substitute for amber or as an elec-

trical insulator. The liquid mixture, after a short heat treatment, may be used as a binder for substances like carborundum.<sup>178</sup>

Esters of inorganic acids, particularly the aryl esters of inorganic oxy-acids, have been used as modifiers of the phenol-formaldehyde resins. Baekeland<sup>179</sup> employed o-cresyl phosphate or a mixture of cresyl phosphates containing a major proportion of the ortho compound. The corresponding silicates, titanates, borates and molybdates also serve as plasticizing agents. As a rule, from 20-60 parts by weight of phenyl ester are added for each 100 parts of the phenol-formaldehyde resin. Ehrenzweig<sup>180</sup> used tricresyl phosphate with hardenable resins having a phenolic base and dissolved the mass in high boiling liquids (triacetin, turpentine oil or glycerol) to make a varnish for coating wires.

Triphenyl phosphate, heated at 320-350°C. with calcium oxide or zinc oxide, resinifies. Small amounts of trioxymethylene are added, corresponding to any phenol that may be liberated. Drying oils may also be incorporated. The product is light amber in color, and is water resistant. It is useful for molding, or in the manufacture of varnish.<sup>181</sup>

#### CELLULOSE ETHERS AND ESTERS

Aylsworth<sup>182</sup> prepared a non-inflammable varnish, for metals, by dissolving a fusible phenol or cresol resin (with or without a hardening agent) and a cellulose ester in a solvent such as acetylene tetrachloride. Softeners (halogenated fatty acids or their esters) and fillers may be added. Bonner<sup>183</sup> dissolved a cellulose ester, e.g., the acetate, in a fluid condensation product of phenol and formaldehyde to form a molding composition.

Cellulose esters were also incorporated with phenol-formaldehyde resin by Jones,<sup>184</sup> who introduced the ester at any stage of the reaction, prior to final hardening. In one procedure, 25 parts of cellulose acetate are dissolved in 212 parts phenol and about 25 parts of a phenol ester added. Then, 212 parts of 40 per cent formalin and about 5 parts concentrated ammonia are introduced and the mixture boiled several hours. The water which separates is decanted and the mass further heated. The product may be used as a coating and fillers may be added.

A mixture of o- and p-hydroxybenzyl alcohol, obtained by condensing formaldehyde or one of its polymers with phenol in the presence of an alkali, with the subsequent addition of an acid such as acetic acid, may be added to compositions having cellulose acetate as a base to regulate the flexibility and durability of films, plates and other articles made from it.<sup>185</sup>

A mixture of viscose, phenol and formaldehyde can be worked or condensed by means of heated rollers, and thus converted into a homogeneous plastic mass, which can be molded or sheeted in a manner similar to rubber. In fact, rubber may be included as one of the ingredients, in which case sulphur may also be added to effect vulcanization under the final action of heat.<sup>186</sup> If, instead of being rolled, these same ingredients are simply heated, solidification takes place and a product resembling shellac in appearance is formed.<sup>187</sup> Fabrics can be waterproofed by coating them first with a rubber composition, then with a layer of cellulose ester

or ether, and finally with a compatible synthetic resin (diphenylolpropane-formaldehyde).<sup>188</sup>

Alkyl ethers of cellulose are suggested as softeners for the synthetic resins. The incorporation of less than 10 per cent ethyl cellulose retards hardening of phenol-formaldehyde compositions.<sup>189</sup> Lilienfeld studied various methods of modifying cellulose ethers, and used a very wide variety of agents, among which were phenolic condensation products.<sup>190</sup> Since the alkyl ethers of cellulose can be made soluble in water, the addition can be made in that solvent.<sup>191</sup> In one method, aqueous solutions of alkyl cellulose ethers were mixed with colloidal dispersions of condensation products made from drying oils and fusible phenol-aldehyde resins. The resins are then converted to the infusible form during or after the manufacture of the film or filaments to give a product which is stable in water.<sup>192</sup> Acetone has also been recommended as a solvent for the homogenizing of cellulose compounds and phenol-formaldehyde resins. In this case, the removal of the solvent leaves a composition which can be powdered, then charged into heated molds to form shaped products.<sup>193</sup> It is also possible to carry out the reaction between phenol, cellulose ester and formaldehyde in the presence of ethyl acetate.<sup>194</sup> The solvent power of phenol for cellulose ethers was utilized by Ushakov<sup>195</sup> to introduce them into the reaction mass, after which formaldehyde and a neutral, acid or alkaline catalyst was added and condensation effected.

Esters of dicarboxylic acids (adipic) have also been used to assist in the preparation of plastic masses from ethyl cellulose and synthetic resins.<sup>196</sup> Weller and Robinson-Bindley<sup>197</sup> effected condensation in the presence of a very small proportion of nitrocellulose or cellulose acetate, the maximum amount of cellulose ester used being about 0.8 per cent of the weight of the phenol. In an example, cresylic acid, formaldehyde, sodium hydroxide and cellulose acetate are mixed, the liquid product is boiled down, baked at atmospheric pressure, and may be further treated in an autoclave. Camphene and nitrocellulose are added to a phenol-formaldehyde condensation product, using acetone as a solvent,<sup>198</sup> to yield a substitute for celluloid. Another way of blending nitrocellulose with a phenol-formaldehyde resin<sup>199</sup> is to treat cellulose with a solution of sulphuric and nitric acid, then, after washing and drying the product, to steep it first in phenol and afterwards in formaldehyde. Finally, 2 per cent of p-dichlorobenzene is added. It is possible to blend phenolic resin with nitrocellulose by reacting phenol with o-benzoyl benzoic acid (in the presence of sulphuric acid), and to mix the reaction product with nitrocellulose and hexamethylenetetramine.<sup>200</sup> The resulting composition is used in lacquers.

A coating composition containing cellulose and synthetic resin can be prepared by mixing cellulose fiber with a varnish formed of a plasticized phenolic resin. After removing the solvent, the residue is rolled until it is homogeneous,

and is thus employed for the preparation of coatings.<sup>201</sup> By treating cresol with allyl alcohol and zinc chloride, Moss and Seymour<sup>202</sup> obtained a resin which was compatible with cellulose acetate.

Compositions containing phenol-formaldehyde and cellulose esters can be made impervious to Röntgen rays or radium emanations by mixing with lead sulphate or lead oxide. For instance, 18 kg. hardenable phenol-formaldehyde resin, 5 kg. wood flour, 5 kg. acetyl cellulose, 70 kg. powdered lead and 2 kg. lead oxide (PbO) are made into a homogeneous mixture.<sup>203</sup> Weber proposed to parchmentize a cellulosic material with sodium zincate, then to treat with phenol and formaldehyde and to condense these substances under heat and pressure.<sup>204</sup>

#### RUBBER-MODIFIED PHENOL-ALDEHYDE RESINS

A hard rubber composition was prepared by Baekeland<sup>205</sup> by mixing with rubber a powdered, brittle phenol-formaldehyde resin representing an intermediate stage of condensation. Catalysts may be present to make the resin infusible on vulcanization of the rubber. Aylsworth,<sup>206</sup> on the other hand, completely hardened a phenol-formaldehyde resin to an infusible and insoluble condition before incorporation with rubber, and exposed the resin in powdered form to a temperature of about 260°C. to remove any free phenol, moisture or ammonia. The hardened condensation product was used in proportions varying between 30 and 90 per cent of the total composition. Vulcanization was carried out at the usual vulcanizing temperature.

Another procedure, recommended by Aylsworth,<sup>207</sup> was the treatment of a hard, porous sponge of a completely condensed product of phenol and formaldehyde by boiling for several hours with a 10 per cent solution of caustic soda or potash. After washing, 2-4 parts of the residue were mixed with 1-3 parts of rubber, sulphur was added and the composition vulcanized by heating. The molded and vulcanized material when used for battery jars containing a strongly alkaline electrolyte was treated with caustic alkali to remove any excess of the vulcanizing agent. Benjamin<sup>208</sup> mixed rubber stock and a vulcanizing agent with asbestos, mica or other mineral filler, the particles of which are coated with a primary soluble resinous condensation product of phenol and formaldehyde, and hardened the mixture by heating. A resilient gasket or packing material can be made from this composition. The completed material contains less than 1 per cent of uncombined sulphur. For the preparation of another rubber composition,<sup>209</sup> commercial phenol is mixed with an equal volume of 40 per cent formalin and 5 per cent ammonia solution, and the mixture is maintained at about 80°C. until a plastic mass results. Twenty per cent of this mass is mixed with 40 per cent rubber, 7-8 per cent sulphur and the usual fillers. The composition is vulcanized for 2 hours at 138°C. A phenolic rubber composition capable of being coated onto cloth or paper and then vulcanized was prepared by Satow.<sup>210</sup> The composition contained phenolic resin, rubber, wood flour, asbestos, sulphur, magnesium carbonate and solvent.

A mixture of rubber, vegetable ivory and phenol-formaldehyde resin in equal proportions was used by Wiechmann<sup>211</sup> as a plastic composition. Rubber or rub-

ber substitute, vegetable albumin and phenol-formaldehyde resin may be incorporated on mixing rolls.<sup>212</sup>

Plauson<sup>213</sup> incorporated rubber with condensation products of formaldehyde and phenol, acetone or furfural by homogenizing the substances in the presence of a liquid which exerts a solvent or a swelling action upon both ingredients (chlorohydrin or cyclohexanol).<sup>214</sup> Fillers, solvents or sulphur may be added and the product vulcanized. To obtain a varnish 20 parts of phenol-aldehyde resin, 5 parts of rubber and 50 parts of cyclohexanol may be used. For a molding mixture, 10 parts of rubber, 90 parts of resin, 30 parts of  $\beta$ -dichlorohydrin and 20 parts of cyclohexanol, with or without fillers and sulphur, may be used, the solvents being expelled by evaporation.

Raw rubber can be mixed with fusible phenol resins on cold rolls or in cooled mixing machines. On heating to 180°C. in molds the material becomes insoluble and has the appearance and characteristic properties of an elastic, light-colored vulcanite. The rubber in such compositions can be vulcanized either by incorporating a small percentage of sulphur in the original mixture or by subsequent surface-vulcanization with sulphur chloride.<sup>215</sup> Hydrocarbon polymers other than natural rubber have been used for incorporation in phenol-formaldehyde resins. Thus the polymers of unsaturated hydrocarbons obtained from cracked petroleum have been employed.<sup>216</sup>

Hopkinson<sup>217</sup> incorporated rubber with vulcanizing, compounding and filling materials by suspending, emulsifying or dissolving the materials in water, adding them in this form to latex, and drying the mixture. Insoluble solids (gums, phenol-aldehyde and other resins, stearic acid, paraffins and waxes) are dissolved in organic solvents and the solutions are emulsified with water. The aqueous mixture may be dried by spraying in a heated atmosphere or in the usual drying chambers and can then be used for molding. Also, latex can be treated with phenol, and formaldehyde added afterwards.<sup>218</sup> If sufficient formaldehyde is added, coagulation takes place.<sup>219</sup> In another proposal a plastic material is obtained from a phenol and an aldehyde which is included in an aqueous dispersion of latex. The mixture is heated in an autoclave to give a product which may be vulcanized.<sup>220</sup> Bradley and Cadwell<sup>221</sup> heated a mixture of rubber, a vulcanizing agent and a condensation product of formaldehyde with an aliphatic amine, and obtained vulcanized products.

McGavack,<sup>222</sup> to produce rubber compositions which can be molded, dissolved 15 kg. of crepe rubber in 400 kg. of carbon tetrachloride and passed chlorine into the solution till the rubber had absorbed twice its own weight. He then added 30 kg. of phenol dissolved in an equal weight of 40 per cent formaldehyde solution and mixed the solutions thoroughly. The mixture was heated for 2 hours under reflux, added to boiling water and the excess of solvent, chlorine, hydrochloric acid, formaldehyde and phenol removed by washing several times. The product was milled, pulverized, dried at 95°C. and then molded at 175°C. under a pressure of about 3000-4000 pounds per square inch. It had a density of about 1.4.

A reaction product resembling hard rubber is formed from rubber and an aldehyde with sulphuric acid as condensing agent.<sup>223</sup> The condensation may also be carried out between rubber, an aldehyde and phenol. Thus vulcanized rubber can be treated, according to McGavack,<sup>224</sup> with a rubber solvent such as benzene and then with chlorine, phenol and formaldehyde in a manner similar to that described to obtain a product resembling hard rubber.<sup>225</sup>

Uncured rubber and a phenol-aldehyde resin can be united by molding under heat and pressure, forming a hard material, according to Warwick and Warwick.<sup>226</sup> Material usable for electrical insulation was obtained by Kulas<sup>227</sup> by adding 100 parts of pulverized scrap or waste rubber or 50 parts of rubber and 50 parts of filler or coloring material to the viscous solution of a phenol-aldehyde condensation product dissolved in 50 parts of acetone or alcohol. The mixture was stirred and gently boiled, the solvent recovered and the residual material rapidly calendered to expel volatile constituents. It was seasoned at 30-40°C. for about 14 days, molded and dried at a temperature gradually increased to 160°C. Finely divided ebonite<sup>228</sup> may be incorporated with a phenol-formaldehyde resin by swelling the ebonite with the molten resin and molding when the gel state is reached.

Naunton and Siddle<sup>229</sup> investigated the possible utility of phenol-formaldehyde and of polybasic acid-polyhydric alcohol (alkyd) resins in soft and hard vulcanized rubber. Phenol-formaldehyde resins are very difficult to disperse during mastication and it was found better to dissolve the resin in concentrated sodium hydroxide, add this to latex, coagulate with carbon dioxide, wash, dry and masticate the finely divided precipitate. Some alkyd resins have a retarding effect on vulcanization and one such resin was found which had pronounced "anti-scorching" power. In hard rubber, phenol-aldehyde resins protect the surface from light, increase the resistance to heat, to hydrocarbon solvents and to mineral oils.

A method for attaching rubber to a rigid material, such as metal, is to interpose a layer of a composition containing phenol-formaldehyde resin and vulcanizable rubber. The application of heat and pressure hardens the phenol-formaldehyde composition and consequently the rubber becomes bound to the metal. The cement is composed of rubber, carbon black, sulphur, methylene p-toluidine and a phenol-formaldehyde condensation product.<sup>230</sup> A cement for uniting resin-impregnated fabric to metal contains a solution of phenol-aldehyde resin and rubber.<sup>231</sup>

#### LIMED COMPOSITIONS

A large number of resinous products contain oxides or carbonates of calcium or magnesium in admixture with phenol-formaldehyde resins. A typical example of such a limed composition is made by treating fusible phenol-formaldehyde resin with calcium hydroxide to convert the phenol groups to phenolates. The cooled or solidified product is mixed with a compound containing active methylene

groups to transform the fusible resin into one which is infusible and insoluble. Filling materials are added, and the product is molded.<sup>232</sup>

Phenol and formaldehyde may be condensed in the presence of mixtures of magnesium carbonate and magnesium oxide. The resinous product is kneaded and molded to form masses resembling yellow ivory,<sup>233</sup> suitable in density for use in the manufacture of billiard balls. When nigrosine and wood flour are also added, and the mixture dried at 75°C. under reduced pressure, a product is formed which can be molded cold under high pressure and hardened at 160°C.<sup>234</sup> To assist in taking up the 4-5 per cent water in the separated resin, plaster of Paris may be added.<sup>235</sup> The procedure is to take 100 parts of crude coal-tar acids, and mix with 120 parts of ground magnesium-formaldehyde mixture (made by grinding in a pebble mill 30 parts of calcined magnesium oxide and 150 parts of aqueous 40 per cent formaldehyde solution). Two hundred parts of saturated brine is added, and the mixture is allowed to stand in the cold with slow agitation until all the formaldehyde is consumed. When the reaction is over, the water is decanted, and the resinous mass is dehydrated by mixing with 54 parts of powdered plaster of Paris. One hundred parts of wood flour containing 2 parts of aluminum palmitate and 2 parts of carbon black are now incorporated by means of a pebble mill.

The temperature and time of heating may be varied<sup>236</sup> in order to alter the properties of the product. In many experiments the temperature during the initial condensation was 90-95°C., and the time of reaction about 30 minutes. A number of substances other than those mentioned above have also been used. Among these are iron oxides, zinc oxide, salts of fatty or resin acids,<sup>237</sup> sodium carbonate and a mixture of sodium carbonate with sodium borate.<sup>238</sup>

In another process,<sup>239</sup> the fusible phenol-formaldehyde resin is heated at 175°C. with a solid basic oxide (CaO, MgO, NaOH) to neutralize the hydroxyl groups of any free phenol or of the resin itself. The product needs no mechanical plasticizing, but can be pulverized, mixed with fillers and a methylene-containing agent, and hot-molded. Portland cement has been mixed with a phenol-aldehyde resin, asbestos and solvents (e.g., acetone, methyl ethyl ketone) to give an adhesive suggested for use with linoleum.<sup>240</sup>

Hexamethylenetetramine is used to assist setting of limed resins in the molding operation, without causing excessively rapid hardening.<sup>241</sup> A method described by Redman<sup>242</sup> calls for boiling in a still for 2 hours at about 200°C., with continuous rapid stirring, 74 pounds calcium hydroxide, 877 pounds phenol-formaldehyde condensation product (from 1.25 mols phenol and 1 mol formaldehyde). The mass is cooled, ground and mixed with 52.5 pounds of hexamethylenetetramine. Then the product is pulverized, mixed with fillers and molded in a hot press. In the initial step (the treatment of the phenol-formaldehyde with lime), it is desirable to calculate the lime addition as substantially equivalent to the hydroxyl of the resin, but a somewhat smaller proportion of lime may be used with good results.<sup>243</sup>

When sulphuric acid is used as the catalyst in the preparation of a phenolic

resin, its disintegrating effect is prevented, Harrison<sup>244</sup> states, by using aluminum or magnesium compounds instead of barium hydroxide and either a barium soap or a soap-forming acid. The basic oxides,<sup>245</sup> hydroxides or carbonates of magnesium, iron, zinc, sodium or potassium in sufficient amount to neutralize all free phenol, are suggested as additions for obtaining good molding properties.

The modifying action of soaps was utilized by Rosenblum.<sup>246</sup> Phenol and formaldehyde are condensed in the presence of zinc oleate or rosinate to the extent of 7.5 per cent (calculated as oxide) of the phenol. Condensation is continued until a resin is obtained which is soluble in varnish solvents. Organic salts of calcium, barium, strontium, sodium, lead, manganese or cobalt may be substituted.

Ellis<sup>247</sup> found that an alkaline-earth base so alters the resin that it becomes particularly adaptable for hot molding. For example, 1 mol of phenol, 0.25 the combining proportion of barium hydroxide and aqueous formaldehyde in an amount equal to the weight of phenol are heated and stirred together at 80-90°C. for 2-3 hours, when the solution is ready to be mixed with a filler.

A synthetic resin, made by condensing a phenol with formaldehyde in the presence of lime, and then in the presence of sulphuric acid, can be mixed with a small amount of montan wax and alkaline catalyst. Hexamethylenetetramine, and fillers, are then added in order to convert the product into a moldable resin.<sup>248</sup>

A molding powder which resembles the limed resins is made up in the following manner: in an open vessel heat a mixture of rosin (4 parts), calcium oxide (1 part) and formalin (4 parts); pulverize the product, and to 450 parts of the powdered mixture add wood flour (300 parts), Portland cement (4 parts) and heavy mineral oil (10 parts) which has been baked to a paste with calcium carbonate (5 parts); harden with about 8 per cent hexamethylenetetramine. Synthetic phenolic resins may be incorporated with the rosin.<sup>249</sup> Resinous compositions resistant to penetration by x-rays or radium rays may be prepared by causing phenolic compounds of lead, uranium, thorium or thallium to react with an aldehyde.<sup>250</sup>

Other products which are similar to the limed phenol-formaldehyde resins are the limed phenol-carbohydrate resins described by Meigs.<sup>251</sup> The phenol-carbohydrate resins are made by condensing phenol with sugar (e.g., dextrose). These resins are subjected to a treatment resembling that by which the limed phenol-formaldehyde products are formed; namely, neutralization with calcium hydroxide, reaction with hexamethylenetetramine, grinding, addition of wood flour and molding at 150-180°C.

#### MISCELLANEOUS MODIFIERS

Various organic acids have been added to phenolic resins, usually in the A (initial) stage of condensation. The purpose which the acid is intended to serve varies widely from case to case, but usually the reaction involved is one of condensation in which hydroxyl groups of the resin take part.

Lactic acid of 50-60 per cent concentration may be incorporated with the initial liquid condensation product of phenol and formaldehyde (in the proportion of 80 parts of the condensation product to 45 parts of the acid) to yield a molding composition. The mixture is heated at 100-110°C. until condensation has proceeded so far that the product no longer adheres firmly to a clean metallic surface. At room tem-

perature this product forms a very viscous syrup, and filling material (asbestos, wood flour or china clay) may be readily added to make a molding composition which can be hardened by baking.<sup>252</sup> Clear, transparent products<sup>253</sup> are made by condensing 1 mol of phenol and 15 mols of formaldehyde in a solution which is sufficiently alkaline for the resin to remain in solution during the condensation, and only such acids or bases as form salts which do not cause turbidity are used as hardening agents. Lactic acid and potash are suggested as being useful for this purpose.

Jäger<sup>254</sup> employed salicylic acid as a modifier (see also Chapter 17). For example, he condensed 1 part of phenol with 22-3 parts of 30 per cent formaldehyde in the presence of 0.35 part of an alkaline salt of a fatty acid (sodium stearate), heated the mass 19 minutes at 70°C., dehydrated *in vacuo* and added 1.8 mols of salicylic acid per 1 mol of alkali. The resin is useful for the manufacture of artificial horn. Castor oil or glycerol may be added.

Pyromucic acid is heated under pressure at 120-150°C., together with phenols and sulphuric, hydrochloric or phosphoric acid. Formaldehyde, or its polymers, and filling materials may also be introduced into the reaction mixture. The products, which are partly soluble in alcohol and acetone and completely soluble in benzene, are used for making a substitute for vulcanite and for the preparation of varnishes.<sup>255</sup> Aylsworth<sup>256</sup> employed a number of organic acid anhydrides, including benzoic, phthalic, acetic and stearic. These absorb ammonia by forming amides, and increase the toughness of the product. Stage A resins have been made from a mixture of phenol, formaldehyde, fatty acids and ammonia. The ammonia combines with the aldehyde. As soon as the soluble resin is formed, the reaction is checked by neutralization of the excess free acid.<sup>257</sup>

By the use of polycarboxylic acids, notably phthalic, naphthalic, diphenic, maleic, fumaric, malic, succinic and tartaric acids, Norton<sup>258</sup> was able to prepare non-turbid resins for the production of so-called non-breakable glass substitutes, transparent fountain pen barrels, and imitations of jewelry stones. For example, 1000 parts of phenol are caused to react with 1000 parts of formaldehyde in the form of a 40 per cent solution, in the presence of 2 parts of sodium carbonate. Fifty to 100 parts of sodium acid phthalate are then incorporated, and the water formed by the reaction is allowed to volatilize. The product is free from turbidity.

When o-phthalaldehydic acid condenses with phenols or phenol ethers, gummy products are formed<sup>259</sup> from which crystalline phthalides can be obtained. The phthalides<sup>260</sup> may be used as plasticizers and softeners not only of phenolic resins, but of the alkyl and urea resins also (see Chapters 11, 31, 47, 53).

Petrov<sup>261</sup> condensed phenol with formaldehyde in the presence of acidic or basic catalysts, and after cooling to 40-50°C. mixed naphthenic acids obtained by the oxidation of petroleum products and then dissolved the resulting semi-fluid substances in alcohol. He proposed their use for insulating varnishes or as a binding material for molding compositions. (See Chapter 16.)

Schmidt<sup>262</sup> employed small quantities of phosphoric or oxalic acid in order to vary the  $p_H$  of phenol-formaldehyde resins. The neutralized plastic resin is brought to a  $p_H$  of approximately 4 or 5 by kneading it with either of these acids.

If a  $p_H$  below 2.5 is maintained during the hardening operation, the product is unstable, and if the  $p_H$  is above 5.5, the hardening under pressure and heat proceeds too rapidly. (See Chapter 16).

Cacodylic acid,  $(CH_3)_3AsOOH$ , has been incorporated with phenolic resins. The object in this case is to produce a resinous coating containing arsenic. Such a coating may be applied when the destructive action of parasites is to be prevented, for instance, on surfaces which are to be exposed to the action of marine growths.<sup>203</sup>

FIG. 72.—Dyeing Machine Made of Haveg.

In preparing insulating compositions for incasing electric coils, Baekeland<sup>204</sup> used solvents boiling above 120°C. such as naphthalene, xylene, nitrobenzene and other hydrocarbons or their homologues or mixtures of these, to reduce the shrinkage of the resin and soften it at high temperatures. He also employed permanently fusible resins, e.g., those from phenol and formaldehyde. Aylsworth<sup>205</sup> used similar substances, and also dinitrobenzene, acetanilide and ricinoleic acid, incorporating these softeners with the resin by mixing at 175°C. Small quantities of softening agents eliminate the brittleness and inflexibility which is an inherent property of hardened phenol-formaldehyde resins. Baekeland also made particles or fragments of an infusible composition containing a phenolic condensation product in solid solution with naphthalene, anthracene or other solvent of high

boiling point, and after transformation into the final state, welded them together into coherent masses under the action of heat and pressure.<sup>266</sup>

Phenol-formaldehyde resins prepared in the presence of 2 per cent camphor, which is subsequently removed by steam distillation, are said to be odorless and non-sticky, pale yellow to dark brown, soluble in caustic alkalis, alcohols, acetone, formic and acetic acids, insoluble in cold benzene and carbonates.<sup>267</sup>

Cyclohexane, cyclohexanol or its esters, and cyclohexanone were used as plasticizers by Elbel and Seebach.<sup>268</sup> The nature of the product is determined not only by the plasticizer but also by the amount of hexamethylenetetramine, which is used as an initial ingredient of the resin.

Sulphur compounds were early used in connection with phenolic resins. McCoy<sup>269</sup> prepared a factice from oil with 5 per cent sulphur monochloride. One hundred and twenty parts of this factice, dissolved in 300 parts of phenol, are added to 320 parts formalin, and the temperature is raised to 100-125°C. until the water is driven off. On further heating, there is formed an insoluble, infusible mass which is resistant to water. Tubes of paper pulp can be impregnated with sulphur-phenol-formaldehyde resin to render them waterproof.<sup>270</sup> Treatment of phenol-formaldehyde resins with sulphur monochloride gives products which are useful for making electrical and thermal insulators.<sup>271</sup>

Modification of phenol-formaldehyde resins can also be accomplished by adding other synthetic resins. Many of these are considered in the chapters of this book (see Chapters 30, 46, 51, 58), where the particular resin is discussed.

Kollek and Engels<sup>272</sup> observed that the polymerization products of alkylene oxides (particularly ethylene oxide) increase the elasticity of phenol-formaldehyde resins. Another suggestion calls for the addition of phenolic resins to resins prepared from sunflower husks. The resultant product may be used in varnishes.<sup>273</sup>

Crystalline hexamethylenetetramine-triphenol, prepared by boiling an alcoholic solution of hexamethylenetetramine and phenol, is a plasticizing agent, and can be used to convert overcured resins into products which can be hot-molded.<sup>274</sup> Resins which are not sufficiently hardened can be made solid by the addition of hexamethylenetetramine.<sup>275</sup> According to McCoy, the catechol tannins are of value in regulating the hardening of resins, especially when it is undesirable to introduce material which has a deleterious effect on the dielectric strength of the resin. The hardening action of the catechols is a result of reaction with formaldehyde, and a catalytic influence.<sup>276</sup>

Phenolic resins can be brought into the form of a water suspension by running them directly from the reaction zone into water, and dispersing with the assistance of gum arabic.<sup>277</sup> When a colloidal solution of a resin is added to a colloidal solution of another resin, or of casein, a fatty acid or a cellulose ester, mutual precipitation of the colloids is likely to occur. The precipitate may be dried, powdered and hot-molded.<sup>278</sup>

The use of dyestuffs for coloring purposes is, of course, common in the resin industry, but their use for the purpose of modification is infrequent. By incorporating a diazo compound with a synthetic resin before completing the condensation, colored resins and oil-soluble dyestuffs were made by Plauson and Vielle.<sup>27</sup> The resins used are those obtained by condensation or polymerization of phenols and aldehydes, or ketones and aldehydes. The products may be used as fat- or oil-soluble varnishes for paper, textile fabrics, leather, wood or metals, or as electrical insulators.

Kessler and Eiffaender<sup>28</sup> proposed a somewhat similar method of making an insoluble dyestuff. As an example, they mixed 60 parts of crystallized 1,4-diamino-anthraquinone with 40 parts of the condensation product of 3 parts of phenol and 1 part of acetic aldehyde and heated to about 80°C. This mass is worked on a roller mill, with the addition of 30 parts of water, until the desired degree of fineness of the coloring matter has been reached. After drying in air and grinding, the material is ready for use. It is adapted for painting on acetate silk. The condensation products of phenol sulphonic acids with formaldehyde may replace the phenol product.

A further use of dyestuffs<sup>29</sup> is the application of a dye containing a reducible CO group (bis-1,2-naphthothnophene indigo) in conjunction with a phenol-formaldehyde resin. In general, indigoid or anthraquinoid dyes are suited to the coloring of phenol-formaldehyde resins.<sup>29,2</sup>

The surfaces of hardened phenolic resins are colored blue or black by cold or slightly warm treatment first with an aqueous solution of p-phenylenediamine and then with hydrogen peroxide.<sup>28</sup>

## Chapter 21

### Uses of Phenol-Aldehyde Resins

#### I. Coatings

In addition to attempts to obtain oil-soluble phenol resins (see Chapter 19) which will replace natural resins in oil varnishes, investigations have been directed also to dissolving ordinary phenol resins directly in volatile solvents to form spirit-varnishes.<sup>1</sup> The difficulty has been that phenol resins in the heat-hardened stage (which is the most desirable for the final film) are insoluble in all ordinary solvents. Consequently phenol-resin spirit-varnishes must be made with the reactive type of phenol resin (resol) dissolved in a volatile solvent. Conversion to the infusible and insoluble state is effected by baking the coating.<sup>2</sup>

A varnish of this type suggested by Baekeland<sup>3</sup> consisted of an alkali-catalyzed phenol-aldehyde condensation product dissolved in a volatile solvent, e.g., alcohol or acetone. A small amount of a basic condensing agent was incorporated in the varnish to assist the transformation into an infusible form when the coating was baked. Another varnish of this type contains a mixture of a volatile solvent, e.g., acetone, and a high-boiling solvent, e.g., amyl alcohol.<sup>4</sup> A mixture of acetone and a cyclic hydrocarbon (e.g., benzene or trimethylene) is employed as the solvent in a phenol-resin spirit-varnish intended to be moisture-free.<sup>5</sup> Alcohol as a solvent was found objectionable in this case since it tends to absorb moisture from the air.

According to Jones<sup>6</sup> a varnish of good penetrating power for porous materials (wood) is obtained by dissolving a pasty phenol-aldehyde condensation product in a mixture of aniline and xylene. Another non-alcoholic varnish is made by dissolving a phenol resin in alcohol, precipitating with moisture-free turpentine and then dissolving the precipitated resin in a mixture of turpentine and amyl acetate.<sup>7</sup>

In previous chapters mention has been made of the use of hexamethylenetetramine as a hardening-agent for phenol resins. Aylsworth<sup>8</sup> suggested varnishes consisting of phenol-formaldehyde condensation products, hexamethylenetetramine or paraformaldehyde, and various solvents, including alcohol, acetone, chloro-

<sup>1</sup> Discussions of the solubility of phenol-aldehyde resins are given by A. A. Drummond, *J. Oil, Colour Chem. Assoc.*, 1925, 8, 62; 1927, 10, 83; *Chem. Abs.*, 1925, 19, 1955; 1927, 21, 2194. A. C. Hopper, *Chem. Age (London)*, 1925, 13, 370; *Chem. Abs.*, 1926, 20, 872.

<sup>2</sup> It was at one time alleged (H. von der Heyden and K. Typke, *Z. angew. Chem.*, 1925, 38, 421; *Chem. Abs.*, 1925, 19, 2277) that 15-16 per cent of the phenol resin volatilizes during the baking process. Later investigations could not confirm this. See J. Scheiber, *Z. angew. Chem.*, 1925, 38, 904; *Chem. Abs.*, 1926, 20, 117.

naphthalene and acetylene tetrachloride. Landt and Adams<sup>9</sup> proposed to eliminate several steps in the preparation of such varnishes by synthesizing hexamethylenetetramine directly in the solvent to be employed for the varnish. One method is to react ammonia with formaldehyde in alcohol to form hexamethylenetetramine and then dissolve a phenol resin in this solution. In another procedure the resin is first dissolved in the alcohol and the hexamethylenetetramine is then produced in the solution.

To prevent the formation of bubbles in a varnish film, Cheetham<sup>10</sup> suggested the incorporation of furfural in phenol-resin varnishes of the reactive type. It was stated that the furfural tended to absorb the ammonia liberated from hexamethylenetetramine during the setting of the varnish. Other advantages reported were that furfural increases the fluidity and penetrating power of the varnish and tends to improve the gloss and elasticity of the film. Advantages in the use of furfural in phenol-resin varnishes were observed also by Redman.<sup>11</sup> The furfural was added to an aqueous alkaline solution<sup>12</sup> of a phenol-aldehyde resin to act both as a hardening agent and as a diluent for the varnish.

The statement has already been made (Chapter 15) that the alkaline-condensation of phenol and formaldehyde yields fusible and soluble resols. Careful heating of the latter converts them to resitols, which are partly soluble and are infusible but soften on heating. Further heating of resitols yields insoluble and infusible resites. These three classes, resols, resitols and resites are also designated A, B and C types, respectively, as has already been explained.

Whereas the majority of spirit-varnishes already mentioned contain resols (because of their better solubility) Elbel and Seebach<sup>13</sup> have suggested solvents for the B type (resitols) to manufacture varnishes intended to give firm and resistant films. Hydrogenated aromatic hydrocarbons, hydrogenated phenols (e.g., cyclohexanol) and cyclic ketones (e.g., cyclohexanone) were the solvents found applicable. One varnish of this type consisted of 75 parts of B stage resin dissolved in 70 parts of decahydronaphthalene and 70 parts of cyclohexanol, solution being effected by boiling under reflux. It was stated that practically the same result is obtained by dissolving a resin in the A stage in solvents of the type mentioned and then heating the solution to convert the resin to the B stage. Another modification of the procedure consists in conducting a phenol-aldehyde condensation reaction in one of the recommended solvents.<sup>14</sup>

Bender<sup>15</sup> prepared an air-drying coating composition from a resinoid made out of phenol, formaldehyde and hexamethylenetetramine. The resinoid was dehydrated and transformed to B stage by heating. The hardening reaction was arrested by addition of butyl alcohol or amyl acetate. After heating the resulting solution to complete transformation to B stage, a low-boiling alcohol or acetone was employed to achieve the desired consistency.

In a method employed by Shono<sup>16</sup> for manufacturing phenol-resin varnish, a phenol-aldehyde condensation is carried out first in an alkaline and then in an acid medium. The product is rapidly chilled (e.g., with ice-water) washed, dried and dissolved in equal parts of ethyl and butyl alcohols. Immediately before the solution is to be employed as a varnish, mineral acid is added to complete the final condensation.

In numerous instances, plasticizers and other synthetic resins have been used to modify the properties of phenol-resin varnishes. For instance the incorporation of dibutyl phthalate or tricresyl phosphate into such a varnish is said to improve the flexibility of the film.<sup>17</sup> Among the synthetic resins which have been incorporated with phenol-resin varnishes are the alkyd resins,<sup>18</sup> the polyvinyl esters<sup>19</sup> and the resin obtained by heating glycerol with sulphates or sulphonic acids (see Chapter 23).<sup>20</sup> Levy<sup>21</sup> has suggested the use of a varnish made by sulphonating a phenol-aldehyde resin and dissolving the resultant product in an appropriate organic solvent.

To form varnishes from insoluble or only partially soluble phenol resins, Plauson<sup>22</sup> suggested dispersing the resin in a solvent by the use of a colloid mill. The same principle was employed by Wakefield<sup>23</sup> to make a non-penetrating varnish. Rubber is reported to act as a protective colloid for stabilizing unstable suspensions consisting of a phenol-formaldehyde resin in gasoline.<sup>24</sup>

#### PHENOL RESINS IN CELLULOSE LACQUERS

In nitrocellulose and cellulose acetate lacquers a certain amount of a natural or synthetic resin is needed to offset two shortcomings, viz., lack of adhesion and lack of luster. Among the resins found useful in this way are those from phenols and aldehydes.<sup>25</sup> In selecting phenol resins for such lacquers their compatibility with cellulose esters must be considered. Hofmann<sup>26</sup> reports that in speaking of compatibility it is necessary to consider the state of affairs existing in a poly-component system. Thus, for example, one speaks of the compatibility of phenol resin with nitrocellulose in amyl acetate and not simply of the compatibility of phenol resin with nitrocellulose. It was noted that although some resins are compatible with nitrocellulose in any solvent, the majority behave differently in different solvents. The observation was also made that certain resins are compatible with nitrocellulose in some solvents only when another particular solvent is present. Clear solutions were obtained with nitrocellulose and an oil-soluble phenol resin (Amberol H-9) dissolved in amyl acetate, butyl acetate, butyl propionate or

butyl Cellosolve. Solutions in ethyl acetate and in acetone were cleared by dilution with toluene and butyl alcohol.

According to Wilson,<sup>27</sup> the viscosity of nitrocellulose solutions can be lowered by adding a phenolic condensation product containing an active methylene compound (e.g., hexamethylenetetramine). On keeping or heating, the viscosity is further reduced.

For coating metal surfaces, Ayisworth<sup>28</sup> suggested a relatively non-inflammable varnish made from a fusible phenol (or cresol) resin and a cellulose ester dissolved in acetylene tetrachloride. Halogenated fatty acids (or their esters) can be used as plasticizers. One method of incorporating cellulose esters is to add them

to the mixture of phenol and formaldehyde prior to condensation.<sup>29</sup> When phenol-formaldehyde condensation products are incorporated with nitrocellulose, cellulose acetate or other added materials,<sup>30</sup> the presence of alkaline-earth bases or alkali cyanides as catalysts causes the formation of an infusible, insoluble and acid- and alkali-resistant varnish when heated in air at 100°C.<sup>31</sup> Phenol-aldehyde lacquers have been made with such esters as cellulose acetate, formate, propionate and butyrate and with methyl and ethyl cellulose ethers.<sup>32</sup> Among the solvents employed are acetone, benzene, toluene, xylene and ethyl acetate.<sup>33</sup> A ketone-phenol-aldehyde resin<sup>34</sup> may replace the phenol-aldehyde body.<sup>35</sup> For this type

of coating, a mixture of a hydrocarbon, an unsaturated hydrocarbon halide and an alcohol serves as the solvent. Naphthalene, diethyl phthalate, triphenyl or tricresyl phosphate, triacetin and thiocarbanilide are suggested plasticizers.<sup>35</sup> For lacquers intended to give light-resistant coatings, Moss<sup>37</sup> has advocated the incorporation of phenol-furfural or ketone-furfural resins in nitrocellulose or cellulose acetate.

The condensation product of formalglycerol with a hydroxybenzyl alcohol is contained in a cellulose acetate lacquer suggested by Seymour.<sup>38</sup> Brushing lacquers have been made which consist essentially of a cyclohexanone-phenol-aldehyde resin, low-viscosity cellulose nitrate, ether, ethyl alcohol and the monoalkyl ether or ester of a glycol.<sup>39a</sup>

An adherent coating composition<sup>38</sup> can be made by mixing cotton flock or  $\alpha$ -cellulose with a plasticized phenol-formaldehyde resin. The reaction product of phenol, tung oil and formaldehyde, admixed with cellulose acetate or formate or with benzyl cellulose, yields another coating composition.<sup>40</sup> Shellac or other natural resins may be added to the product obtained to increase its efficiency as a sheet veneer. A similar coating comprises ripened cellulose acetate, a phenol resin (Novolak) and acetone and ethyl alcohol as solvents.<sup>41</sup> No halogenated hydrocarbons are needed as solvents in this lacquer. A varnish proposed by Frederic<sup>42</sup> contains a mixture of natural resins, phenol-aldehyde resin, collodion, powdered mica and alcohol. Before applying lacquers containing cellulose ester, the surface can be primed with a lacquer containing a phenol-formaldehyde condensation product and an alkyd resin.<sup>43</sup> The addition of an acid catalyst is sometimes required. To make a nitrocellulose or cellulose acetate film relatively fire-proof, the application of a phenol-aldehyde coating has been suggested.<sup>44</sup>

To form a polishing composition for cellulose lacquer surfaces one proposal consists in mixing together a cellulose ester, a phenol-aldehyde resin, benzene, ethyl phthalate (plasticizer) and an abrasive.<sup>45</sup>

The suggestion has often been made to employ resin-modified cellulose lacquers as insulating-coatings. For instance, Hull<sup>46</sup> covered wires with a composition containing cellulose acetate (30 parts), a phenol resin (10 parts) and furfural (300 parts). For a similar purpose Schnable<sup>47</sup> employed a cellulose acetate-phenol resin lacquer and then applied as an outer coating a mixture of ozokerite and castor oil. The laminated insulation thus formed was subjected to a baking treat-

ment. A wire enamel suggested by Ehrenzweig<sup>44</sup> contains phenol-aldehyde resin (A stage), tolyl phosphate, turpentine, dicresylin and a cellulose ester.

#### APPLICATIONS OF PHENOL-RESIN SOLUTIONS

Numerous proposals have been made for the use of phenol-resin varnishes in all types of protective coatings, particularly for metals.<sup>45</sup> In addition, these solutions have been employed to impregnate paper and fabrics for insulating-media and for the manufacture of laminated boards and gears (see Chapter 22).

In applying a phenol-aldehyde resin coating to metal one of the chief points of interest is the acid- and corrosion-resistance of the finished material.<sup>50</sup> A study of the factors influencing the chemical resistance of phenol-aldehyde resins has been made by Sokolov.<sup>51</sup> This work reveals that the time-duration and temperature of condensation determine very slightly the ability of the ultimate resin to withstand chemical action. However, the type of condensing agent is an unimportant factor, provided it is present in proportions of not more than 10 per cent. When more than this amount of condensing agent is used, the resulting resin is more hygroscopic and offers less resistance to dilute acids. Resistance to chemical reagents is lowered by: (1) acid condensing agents (even when neutralized later); (2) the presence of alcohol; (3) decreasing the proportion of formaldehyde in the reaction mixture.

One of the earliest uses suggested for phenol resin solutions was the coating of the inside of metal food-containers.<sup>52</sup> Investigations have shown that a film of phenol resin on a metallic container prevents the catalytic effect of the metal in promoting rancidity of fats stored in the container.<sup>53</sup>

The protection afforded against fatty acids has suggested the use of phenol resin to coat metallic filter cloths apt to come in contact with such acids.<sup>54</sup>

In most instances it is important that a coating should adhere well to the surface covered, so that vibrations of any sort will not endanger the protective action.<sup>55</sup> It has been reported that hammer-proof and acid-proof coating for steel pipe is obtained by pickling the surface before dipping the pipe in the phenol resin solution.<sup>56</sup> Phenol reacts with easily oxidizable metals, producing a surface to which a lacquer can cling tenaciously. Michel<sup>57</sup> made use of this principle by incorporating an excess of phenol in a phenol-resin varnish intended for metals. Jones<sup>58</sup> suggested an undercoat of a linseed oil varnish to secure good adherence of phenol-aldehyde films. Another proposal is to etch a metallic surface with magnesium chloride solution. Any magnesium chloride adhering to the surface is con-

verted into magnesium hydroxide and oxide. Then a solution of phenol and formaldehyde is applied and changed into an insoluble resin by heat.<sup>60</sup>

In order to secure good adhesion of phenol resin coatings on metals, Townsend<sup>60</sup> recommended that the surface be coated with a thin film of another metal. This is accomplished by employing a solution of a metal lower in the electromotive-force series than the metal to be coated. Thus iron is given a coating of copper by applying copper chloride solution. In the method suggested, a varnish is prepared by dissolving cupric chloride and a phenol-aldehyde resin in methyl or ethyl alcohol.<sup>61</sup>

Baekeland<sup>62</sup> stated that lack of adherence of phenol resin coatings is caused by a slight shrinkage during the hardening process. He suggested the inclusion of finely divided inert material (e.g., asbestos, clay, sand) to minimize the contraction of the film.

A great number of the proposed phenol-resin coatings for metals contain inert material for various reasons. For example, in coating aluminum parts for automobiles, the metal pores should be sealed according to Peterson.<sup>63</sup> This purpose is accomplished by a phenol-formaldehyde resin mixture containing 10 per cent of aluminum silicate. Aluminum may also be protected by using an undercoat of wax and a final coating of resin. The wax is volatilized and coating burned into the metal by heating to 250-400°C.<sup>64</sup> A primer containing titanium dioxide and a phenolic resin has been found to be good for magnesium alloys.<sup>65</sup>

To produce a finish of enamel-like character, a liquid phenol-formaldehyde condensation product is mixed with sodium silicate, casein waste being added as a protective colloid to prevent precipitation of silicic acid.<sup>66</sup> An enamel which dries at ordinary temperatures to form a hard film contains a phenol resin, hydrochloric acid as a hardening agent and powdered talc as a filler.<sup>67</sup>

In covering metals with phenol-aldehyde resins, Kränzlein and Müller<sup>68</sup> employed two or more layers of material. The underlying coat contained relatively soft filling materials (e.g., graphite, talc, asbestos) to impart flexibility. The top layer consisted of a phenol resin solution to which hard filling materials (e.g., silicon, quartz) had been added to give the coating mechanical and chemical resistance. In another proposal the preliminary coat consisted of an anti-corrosive paint, the second a casein paint and the final coating was a fusible phenol resin.<sup>69</sup>

Wirth<sup>70</sup> coated metals with a layer of phenol-aldehyde resin, followed by a sheet of asbestos. After this had been hardened with heat another coating of phenol resin was applied to the asbestos and also heat-hardened. Instead of applying the layer of inert material in sheet form, the asbestos may be mixed with the first

coating of phenol resin.<sup>71</sup> It is stated that coatings built up in this manner with alternate layers of phenol resin and of a phenol resin-inert filler mixture are readily repaired in case of damage, since fresh applications of resin will adhere easily to the rough intermediate layers.<sup>72</sup>

When mixed with the proper filling materials (graphite, silica, etc.) phenol-resin coatings have found use in containers for hydrofluoric acid,<sup>73</sup> sulphur chloride<sup>74</sup> and luminescent paints.<sup>75</sup> An impervious coating composition for metals, as proposed by White,<sup>76</sup> consists of a mixture of phenol resin, rubber and sulphur in aqueous dispersion. The preparation of lacquers comprising phenol-aldehyde condensates (or other synthetic resins) and carbon black is described by Wiegand.<sup>77</sup>

For accelerating the hardening of phenol-aldehyde resin coatings, certain metallic oxides (lead dioxide or manganese dioxide) have been suggested.<sup>78</sup> Silicon and graphite are incorporated to increase acid-resistance. An acid-resistant coating composition used by Klas<sup>79</sup> consists of a tar-oil solution of phenol resin to which finely powdered quartz has been added. The metal to be coated is heated to a high temperature before the composition is applied, thereby facilitating the hardening process. To eliminate bubbling and blistering when coatings are thus applied, small amounts of acetic acid, cresol or glycerol are said to be effective.<sup>80</sup>

Phenol-resin solutions have found some application as insulating-varnishes, particularly as coatings for electric condensers. This is of course simply a variation in the employment of phenol resins for insulation as described in Chapter 22. One varnish of this type consists of a mixture of a phenol-aldehyde resin in alcohol with paraffin oil in amyl acetate. The coating dries to a rubber-like consistency.<sup>81</sup> Another coating for condensers consists of successive layers of shellac and phenol resin.<sup>82</sup> In coating electric condensers with phenol-aldehyde resins, Kempton<sup>83</sup> suggested that the hardening be carried out in several stages of alternate heating and cooling, to prevent damage to the condenser laminations. An electrical resistor may be made by applying a mixture of phenol resin and graphite to a fibrous strip.<sup>84</sup> Dumert<sup>85</sup> employed a different procedure by utilizing a colloidal mixture of graphite and resin on a rod of insulating material. The coating was hardened by heating at 150°C.

Baekeland and Thurlow<sup>86</sup> proposed the use of phenol-aldehyde resin solutions as coating compositions for wood. After the coating has been applied, the surface of the wood is pressed against a smooth metal sheet heated to the proper tem-

perature to harden the resin. If a decorative effect is desired, the metal sheet is provided with an embossed design. During the baking of resin-coated wood, blistering of the film may occur from the expansion of air and water vapor in the pores of the wood. To avoid this, Aylsworth<sup>87</sup> heated the wood for several hours at 105-120°C. and then applied the coating while the article was still hot. Essentially the same purpose was accomplished by Buffum<sup>88</sup> by coating wood with molten rosin to expel air and moisture. The subsequent layer of phenol resin was then hardened at a temperature below the melting point of rosin. The statement has been made by Hunt<sup>89</sup> that phenol-resin varnishes are superior to ordinary spar varnishes in retarding moisture changes in wood. No material has yet been found which will entirely prevent such changes. For making wooden rollers, bobbins and poles used in textile industry water- and acid-proof, water and air in the wood are first removed by treatment with alcohol. The phenol-formaldehyde coating composition is then applied and stoved at 150°C.<sup>90</sup> A method that differs somewhat from the above procedures consisted of partially polymerizing a preliminary coating at 40-50°C., applying a second coat and then changing to the infusible state by heating to 140-150°C. This process is reported to give a durable acid-proof surface.<sup>91</sup>

By grinding a natural gum (gum arabic or tragacanth) with a fusible phenol resin in a colloid mill, Tuchfarber<sup>92</sup> obtained an aqueous dispersion to be applied to wood as an undercoating for ordinary varnish or lacquer. It was stated that this treatment imparted a decorative finish and at the same time rendered the wood impervious to moisture.

To prevent discoloration of ebonite panels by the action of light, a coating of phenol-aldehyde resin has been proposed.<sup>93</sup> Layers of this resin are applied to concrete to render it impervious to water and oils.<sup>94</sup> By incorporating various toxic materials in phenol-aldehyde resin solutions, anti-fouling paints are obtained.<sup>95</sup> The toxic agents include phenol, cacodylic acid and salts of copper, mercury and arsenic. Anti-fouling varnishes are employed principally to prevent barnacles and fungous growths from accumulating on structures submerged in sea water.<sup>96</sup>

Solutions of phenol resins have been suggested for impregnating paper to give it transparency.<sup>97</sup> Such material is intended for photographic films and for trans-

parent wrappings. Coating viscose films (Cellophane) with a phenol resin is said to improve heat- and moisture-resistance and to increase the dielectric strength.<sup>106</sup> Films of cellulose esters, coated with phenol resin, were employed by Drew<sup>99</sup> as packaging material. A stencil sheet suggested by Horii<sup>100</sup> consists of yoshino paper impregnated with a solution of phenol-aldehyde resin, nitrocellulose, stearin and castor oil in alcohol or amyl acetate. Another coating composition for stencil paper proposed by Carr<sup>101</sup> contains 10 parts of a 45 per cent solution of a phenol-formaldehyde resin, 2 of aluminum stearate, 14 of chlorinated rubber and 13 of corn oil.

Transfer paper (for imprinting decorative designs on various objects) can be made by coating paper with a phenol-aldehyde resin, a fusible wax, vegetable oils and pigments.<sup>102</sup> Cellulose acetate may also be added to these coating compositions.<sup>103</sup> A carbon paper has been made by applying a mixture of purple lake, china clay, a phenol-aldehyde resol, cyclohexanol, acetone and methylated spirit to a carrier sheet.<sup>104</sup>

Insulating sheets may be formed from threads of spun paper after impregnation with a binder consisting of a phenol-aldehyde resin.<sup>105</sup> Waterproofed fiber tubes have been made by filling the pores with sulphur and coating with a phenol-formaldehyde resin.<sup>106</sup>

The principal outlet for fabrics impregnated with phenol resins is in the manufacture of laminated articles (see Chapter 22). To some extent resin-coated fabrics find other uses. For instance, fabrics for aircraft (e.g., balloons) have been impregnated with phenol resin to render them impervious to gases.<sup>107</sup>

To make fabrics crease-proof it has been suggested that they be coated or impregnated with a solution of a phenol resin.<sup>108</sup> The properties of fabrics are said to be improved by treatment with solutions of phenol resin and salts of aluminum, zirconium, tin or zinc.<sup>109</sup> Phenolic coating compositions are said to make cloth waterproof.<sup>110</sup> Aqueous solutions of phenol resin have been employed by Hochstetter<sup>111</sup> to make cloth flameproof. Other related uses for phenol-aldehyde

resins include treatment of gut for tennis rackets<sup>112</sup> and impregnation of fabrics for rubber-coated tires.<sup>113</sup>

Artificial leather has been fabricated from interfelted cellulose fiber by saturation with an aqueous dispersion of rubber, drying and then impregnating with a phenol-formaldehyde resin. The final product is duly obtained by curing at elevated temperature.<sup>114</sup> Leather coated with phenol-formaldehyde resins resists water-penetration but tends to be brittle.<sup>115</sup> DeVries<sup>116</sup> suggested that a coating composition containing phenolic resin be used for coating rubber or rubber-surfaced fabrics.

In preparing a substitute for glass, Moss<sup>117</sup> employed a metallic screen coated with a cellulose acetate film. One disadvantage was the penetration of moisture through the film, resulting in rusting of the screen. To obviate this difficulty, Moss suggested that the screen be coated first with a light-resistant phenol resin (e.g., diphenylol propane-ketone resin) and then with the cellulose ester.

The use of colored phenol-aldehyde solutions for coating electric-light bulbs has been proposed.<sup>118</sup> Azo dyes are among the substances used in preparing colored phenol resin varnishes.<sup>119</sup> One method of adding fillers and coloring material to such varnishes is to knead them with the phenol resin under pressure and at a temperature at which the resin is in a semi-liquid state. This mixture is then dissolved in appropriate solvents.<sup>120</sup>

Fusible phenol-formaldehyde resins have been included in inks.<sup>121</sup> An ink for printing on fruits contains a phenolic solution of spirit color, a phenol-formaldehyde resin, amyl acetate, ethyl alcohol and a color lake.<sup>122</sup>

One of the interesting applications of phenol resins is in photographic processes, e.g., photo-engraving. In a method employed by Doelker<sup>123</sup> a metal plate is coated with an alkali-soluble phenol resin (stage A) sensitized with ammonium dichromate. The light-sensitiveness is increased by incorporating proteins. The portions of the layer exposed to light become insoluble in alkalies and therefore remain on the plate when a solution of potassium hydroxide is applied. After removal of the alkali-soluble portions the surface under the image is etched with an acid. In similar methods, compounds capable of liberating halogens (e.g., iodoform) when exposed to light are employed as sensitizers.<sup>124</sup>

## Chapter 22

### Uses of Phenol-Aldehyde Resins

#### II. Moldings

Phenol-formaldehyde curing resins were commercially introduced toward the end of the first decade of this century.<sup>1</sup> At that time, the molding industry had reached very substantial proportions. Hard rubber,<sup>2</sup> natural resins and asphaltic compounds were all being utilized. Celluloid had attained a great popularity and the consumption of shellac (largely in the phonograph-record industry) taxed the production. However, shellac was advancing in price and was open to criticism on account of its low water-resistance and relatively low melting point. Both are decided weaknesses in the field of electrical insulation. Further, the fire hazard which is inherent in celluloid was undesirable. Therefore, it was a natural step to try the phenol-formaldehyde condensation products in the established fields.

The commercial success of the phenolic resins has been largely due to the work of Baekeland. He found that the initial condensation product (Bakelite A),<sup>3</sup> when pressed in a hot mold, was transformed into an infusible, but still relatively brittle, Bakelite B. The article could then be removed, replacing the mold in use. When a number had accumulated, the moldings were placed in a "Bakelizer"<sup>4</sup> where they were submitted to heat and pressure to complete the conversion to Bakelite C.<sup>5</sup> As finally obtained the molded objects were infusible, unattacked by nonoxidizing acids and inert to alcohol, acetone, paraffins and esters.<sup>6</sup> Such a procedure eliminated the lengthy drying processes used by the previous workers and so enabled accurately formed objects to be turned out rapidly.<sup>7</sup> The discovery

<sup>1</sup> Some of the earlier applications of the phenol-formaldehyde condensation products are found in Chapter 18.

<sup>2</sup> Concerning the improbability of phenol resins replacing hard rubber, see *India Rubber World*, 1929, 79, 70.

<sup>3</sup> See Chapter 15 for a discussion of the preparation and properties of Bakelite A, B and C.

<sup>4</sup> This apparatus is simply a container in which phenol-formaldehyde resins can be heated under pressure in an atmosphere of carbon dioxide or other gas. (See Fig. 57). The tendency of the molding to become spongy due to the escape of formaldehyde and water is counteracted by the pressure. Bakelizers have been used experimentally but have found very few commercial applications.

Chase, *Elec. Mfg.*, 1932, 10 (4), 20; *Chem. Abs.*, 1933, 27, 377. J. Geller, *Brennstoff-Chem.*, 1933, 13, 130; *Chem. Abs.*, 1932, 26, 6163. For reviews of the patents and discussion of the Bakelite patents as examples of double patenting, see R. Eller, *Kunststoffe*, 1916, 6, 45; *Chem. Abs.*, 1916, 10, 1377. C. Coffignier, *Rev. chim. ind.*, 1917, 26, 201; *Chem. Abs.*, 1918, 12, 96. O. Kausch, *Kunststoffe*, 1914, 4, 263; *Chem. Abs.*, 1914, 8, 3244. J. Ephraim, *Kunststoffe*, 1922, 12, 2, 53. J. Scheiber and S. Hamburger, *ibid.*, 1922, 12, 42.

<sup>6</sup> Laminated phenolic-resin bubble caps have shown their ability to outlast iron in a solvent-recovery plant providing they did not come into contact with boiling furfural or cresol concentrates, strong alkalis or oxidizing acids. G. W. Clark, *Chem. Met. Eng.*, 1934, 41, 542. Vessels made from phenol-formaldehyde condensation products are said not to affect the flavor of foods. British P. 291,403, 1927, to Bakelite Corp.; *Chem. Abs.*, 1929, 23, 1228.

<sup>7</sup> The possibility of eczema due to handling phenol-formaldehyde condensation products has been raised by O. Sachs (*Wiener klin. Wochschr.*, 1921, 34, 356; *Chem. Abs.*, 1922, 16, 2925) and W. Meyer (*Farben-Chem.*, 1933, 4, 453; *Chem. Abs.*, 1934, 28, 1205. *Pharm. Ztg.*, 1934, 79, 1148; *Chem. Abs.*, 1935, 29, 519). However, according to F. Pabst (*Farben-Chem.*, 1934, 5, 127; *Chem. Abs.*, 1934, 28, 3604), the cases reported are due to the extraordinary sensitiveness of the victims to phenol and formaldehyde.

of a resin which would cure in a mold represented a very important advance for the plastics industry.

### INCORPORATION OF FILLERS

Molding powders are made by incorporating the filler in the following ways:\*

1.) The powdered resin is ground together with the hardening agent, lubricant<sup>9</sup> and dye. This may be done by passing the ingredients several times through a high-speed grinder or by using a ball mill.<sup>10</sup> A typical set of proportions is given in Table 28.

TABLE 28.—*Typical Proportions for a Phenol-Formaldehyde Molding Powder.*

Ingredient	Parts by Weight
Resin . . . . .	45 0
Hardening agent . . . . .	4 5
Lubricant . . . . .	1 0
Dye . . . . .	0 5
Filler (wood flour) . . . . .	49 0
	<hr/> 100 0

The filler is added and blending continued until an intimate, uniform mixture is obtained. The material is then sheeted on hot rolls. No definite procedure for sheeting can be given as the technic varies with each composition and the particular molding requirements. The size and speed of the rolls is likewise a factor and a change from one set to another with the same composition almost always necessitates a change in the procedure. The milling step in general is to heat the rolls to a surface temperature sufficient to flux the binder and to regulate the distance between them to the best thickness of sheet. Enough composition is then put into the nip of the rolls to form a complete sheet about the circumference of one roll. The material will adhere to both rolls at the start but will gradually accumulate on one. When the resin begins to flux, as indicated by a change in color of the material, it is scraped off. By repeating the operation a number of times, a uniform sheet is gradually built up and when the composition has the required flowing and curing properties as determined by an actual molding test, it is removed and allowed to cool. By maintaining a constant temperature and a definitely timed sequence of operations, consecutive sheets having practically the same properties may be obtained. The cooled sheets<sup>11</sup> are broken into fragments and granulated to form a molding powder. One disadvantage of this method of blending resin and filler is the fact that only a mechanical mixture is obtained and a more intimate union is possible by other means described below.

2.) The filler can be incorporated with the binder before the condensation of the latter has been carried to the point where the product is solid. That is, one makes use of what is called the liquid A stage.<sup>12</sup> If the initial condensation product is prepared without the use of a catalyst, more aldehyde and an acid

\* In Chapter 65, a fuller account of the preparation of molding powders is given.

<sup>9</sup> E. E. Novotny and C. J. Romieux (U. S. P. 1,557,318, Oct. 13, 1925; *Chem. Abs.*, 1926, 20, 97) proposed to use lanolin as a lubricant.

<sup>10</sup> R. Hessen, French P. 713,976, 1931, to A. Nowack A.-G.; *Chem. Abs.*, 1932, 26, 1811.

<sup>11</sup> F. A. Upper (U. S. P. 1,963,253, June 19, 1934, to Bakelite Corp.; *Chem. Abs.*, 1934, 28, 5200. See also Carborundum Co., British P. 411,846, 1932, to Bakelite, Ltd.; *Brit. Chem. Abs. B*, 1934, 718) incorporated abrasive fillers with phenol-formaldehyde resins in the above manner and cut grinding wheels from the resulting sheet.

<sup>12</sup> French P. 700,853, 1930, to Robert Bosch A.-G.; *Chem. Abs.*, 1931, 25, 3782. (Ebonite filler) German P. 402,707, 1921, to "Esgam" Erfindungs- & Studien-Gesellschaft allogener Materialien m.b.H.; *Kunststoffe*, 1925, 15, 123.

catalyst are included in the composition.<sup>13</sup> A liquid reactive resin has also been used as a wetting agent to facilitate the incorporation of additional solid binder.<sup>14</sup> Similarly, Novotny<sup>15</sup> heated abrasive grains in an oven and mixed them while still hot with 5 per cent of powdered resin. The mass was stirred while cooling, coating each granule. The coated material could be stored until needed. It was then wet with a liquid resin (0.2-5.0 per cent of the weight of abrasive) and enough powdered solid binder to bring the concentration of the latter up to 17 per cent was incorporated. The mass was sieved, formed in molds and heated in an oven to complete the reaction.

3.) Various organic solvents may be used to assist in the thorough mixing of the phenolic condensation product and filler. Alcohol,<sup>16</sup> Cellosolve,<sup>17</sup> furfuryl alcohol,<sup>18</sup> high-boiling hydrocarbons,<sup>19</sup> gasoline,<sup>20</sup> and hydrogenated phenols<sup>21</sup> have all

Fig. 74.  
An Asbestos - Braiding  
Shuttle Made of Bake-  
lite.

Courtesy Bakelite Corporation

been suggested. There are three ways in which the solvent may be employed: 1.) the filler may be wet with the liquid and dry binder added, 2.) the resin may be dissolved, the filler impregnated and the solvent evaporated or, 3.) part of the filler may be impregnated, dried and mixed with the rest. The last is stated by Loetscher<sup>22</sup> to be a cheap and satisfactory method of working. If the resin solution is heated until the condensation has reached the B stage, the resulting composition will mold faster<sup>23</sup> and be less tacky.<sup>24</sup> Tackiness can also be diminished by dissolving a dry brittle resin in the coating for the filler.<sup>25</sup>

4.) Some of the condensation products of phenols and formaldehyde retain part of their phenolic characteristics. Such bodies can be dissolved in aqueous alkali, mixed with a filler and then precipitated on it by acidification.<sup>26</sup> Peabody<sup>27</sup>

<sup>27</sup> J. C. Peabody, U. S. P. 1,083,755, Jan. 6, 1914; *Chem. Abs.*, 1914, 8, 871. Mention is made in

employed water as a wetting agent by adding the binder to paper pulp while on the beater. The paper on being formed into sheets carried the resin with it. Another procedure for incorporating a resin with paper pulp mixes a plastic condensation product with such fillers as slate dust, clay and pigments before kneading in wet fibrous material. Water is added finally to reduce the mass to a pulp.<sup>28</sup>

It has been stated that a thorough impregnation of the filler can be obtained by using emulsions.<sup>29</sup> Cheetham<sup>30</sup> drew resins directly from the reaction vessel into water containing gum arabic or other stabilizing agent. For example, 33 parts of the reactive phenol-aldehyde resinous material formed by refluxing 100 parts of phenol with 80 parts of 37.5 per cent formaldehyde solution and 0.5 part of sodium hydroxide for 30-90 minutes was mixed with 66-200 parts of water and 1-10 parts of gum arabic and passed through a colloid mill. The advantages which are stated to result from the use of aqueous emulsions are elimination of fire hazard, more rapid drying of the mass and more uniform distribution of the resin throughout the filler. According to Seebach,<sup>31</sup> the emulsions which he prepared by using a small amount of water (less than the amount of the resin) and less than the amount of alkali required to dissolve the resin could be broken by the addition of more water. In this way he precipitated the binder upon the filler.

5.) Furfural, benzaldehyde and other high-boiling aldehydes have been used as wetting agents. These substances act not only as solvents, but also as plasticizers and as supplementary hardening agents. Thus, Turkington<sup>32</sup> added 10 parts of furfural and about 8.3 parts of hexamethylenetetramine simultaneously to 100 parts of wood flour in a steam-heated kneading machine. To this mixture, 110 parts of a resin formed from 7.5 mols of phenol and 6 mols of formaldehyde were added slowly. The temperature throughout was held at about 100°C. The mass after cooling was ground and used as a molding powder. Other methods add furfural after partially mixing the dry resin and filler<sup>33</sup> or wet the binder with benzaldehyde before incorporating the diluent.<sup>34</sup>

6.) It has been stated that the amount of filler can be increased up to 95 per cent by incorporating it with the resin in the course of formation.<sup>35</sup> Nash<sup>36</sup> reports that a better control is had over the course of the reaction when the latter is carried out in the presence of solid diluents. Thus, a mixture of 50 parts of asbestos, 16.75 parts of cresol and 3.3 parts of hexamethylenetetramine was prepared. This composition was heated to not above 80°C. while stirring to ensure a uniform reaction. When the condensation had progressed to the desired extent, it was necessary only to discontinue heating to stop the reaction. Rolls of paper have been impregnated by passing first through an aqueous solution of hexamethylenetetramine, drying and then impregnating with a mixture of drying oil and phenol. The paper was heated finally to 100°C. or slightly above.<sup>37</sup>

**Inorganic Fillers.** Asbestos has been used extensively as a filler in moldings which must have considerable chemical resistance.<sup>38</sup> Aylsworth<sup>39</sup> stated that an asbestos-resin matrix withstood compression and did not have such a large coefficient of expansion as the phenol-formaldehyde condensation product itself. The material known as "Haveg" also contains asbestos and has proven useful in the manufacture of chemical apparatus.<sup>40</sup> The tensile strength is said to be about 2500 pounds per square inch; the transverse, 5500 pounds per square inch and the compressive, 10,500 pounds per square inch. This is sufficient to enable quite large vessels to be built, but in case greater mechanical strength is needed, metallic supports are employed (see Fig. 75).<sup>41</sup> Haveg is resistant to many chemicals, the principal exceptions being the strong oxidizing acids, hydrofluoric acid, bromine, iodine, caustic alkalies, acetone and aniline. A special grade is made which does not contain asbestos and is used where resistance to fluorides is required. Wirth has developed methods for coating the inner surfaces of pipes,<sup>42</sup> for covering solid surfaces (metal) with asbestos impregnated with phenol-formaldehyde resins,<sup>43</sup> for constructing large apparatus consisting of several sections,<sup>44</sup> and for building large apparatus reinforced with metal.<sup>45</sup> He has also prepared an acid-proof cement to be used in fastening together pieces of Haveg.<sup>46</sup> This cement was made by adding an acid to a liquid phenol-aldehyde condensation product shortly before use.

Brake linings have been made from asbestos-filled phenol-aldehyde resins<sup>47</sup> and from mixtures of them with powdered iron,<sup>48</sup> lead<sup>49</sup> and vulcanized rubber.<sup>50</sup> A binder prepared by heating for 2-6 hours at 100-200°C. a mixture containing phenol (100 parts), formaldehyde (60-120 parts), oleic acid (20-60 parts) and ammonium oleate (1-15 parts) was proposed by Chapell.<sup>51</sup> With asbestos or powdered talc, mica or lead, it was to be used as a packing for steam pipes.

A mixture of asbestos and mica has been employed by Nash<sup>52</sup> in preparing a composition to be used for parts of fluid-meters. The filler constituted at least 60 per cent of the mixture and contained 5 per cent of mica. Mixed with asbestos, graphite, wood flour or powdered metals, mica has been used in making rubber-vulcanization molds.<sup>53</sup> One of the principal applications of mica has been in elec-

Fig. 75.

number of self-lubricating bearings have been made.<sup>56</sup> Kempton<sup>57</sup> molded pulleys with a graphite-containing insert at the center whereas Volet<sup>58</sup> added graphite and a good electrical conductor (powdered copper) to phenol-formaldehyde resins to make brushes for motors.

Since the early days of the phenol-aldehyde resins there has been a great advance scored in the manufacture of abrasive articles. Improvement became imperative as grinding wheels in industry are being run at higher speeds, in order that increased rates of production may be established. Wheel bonds, therefore, must be made stronger, tougher and more uniform, in order to maintain a sufficient factor of safety. Phenol-formaldehyde-bonded wheels for rough grinding of steel castings (so-called "snagging") have been made which can be safely operated at a peripheral speed of 9000 feet per minute.<sup>59</sup> Both the vitrified- and shellac-bonded wheels have been largely displaced by those containing synthetic resins. Grinding wheels are employed in the automobile industry for numerous operations in many cases displacing circular saws. A number of abrasives have been suggested, carborundum, emery and corundum being the commonest.<sup>60</sup> A typical mixture contains 3-10 parts of abrasive grains and 1 part of phenolic binder, the latter being filled with 5-35 per cent of finely divided Cellite, fuller's earth or powdered quartz. By adjusting the pressure under which the mass is compacted varying degrees of porosity may be obtained.<sup>61</sup> Trivalent metal oxides, e.g., aluminum, chromium and ferric oxides, prepared by calcining the corresponding hydroxides, have been utilized in making polishing wheels from phenol-condensation products.<sup>62</sup> A further use of abrasive-filled phenol-aldehyde resins is the production of safety-treads.<sup>63</sup>

A number of inorganic fillers remain to be mentioned. Potassium chlorate (or perchlorate)<sup>64</sup> is employed to make heaters for blasting-cartridges. Phenol-formaldehyde resins have been used as binders in waterproof matches.<sup>65</sup> The addition of manganese dioxide (0.5-5.0 per cent) to molding compositions is said by Novotny<sup>66</sup> to improve flow and plasticity and to keep the molds in a clean and polished condition. Shields which are opaque to x-rays have been made using 75-95 per cent of barium sulphate.<sup>67</sup> Iron and steel fillers have been incorporated when magnetic properties were desired as in the construction of cores for induction coils<sup>68</sup> and diaphragms for telephones.<sup>69</sup> In the latter case, paper pulp was

<sup>69</sup> J. M. Taylor, U. S. P. 1,514,406, Nov. 4, 1924, to Diamond State Fibre Co.; *Chem. Abs.*, 1925, 19, 157.

included as an additional filler. Noftzger<sup>70</sup> reports that bearings can be produced from 60-80 per cent of a schist which is found at Buckeye, Ariz., held together with a phenol-aldehyde binder. Pencils have been made using talc as a lubricant and eosin as the coloring agent.<sup>71</sup> Electrical insulation has been prepared by driving off a phenolic binder at 1100°C. from a talc-filled composition.<sup>72</sup> Further, charcoal and coke,<sup>73</sup> powdered stone,<sup>74</sup> cement,<sup>75</sup> slag<sup>76</sup> and calcined magnesia with a solution of zinc sulphate<sup>77</sup> have all been suggested as ingredients in plastic masses of the phenol type.

**Organic Fillers.** The commonest organic filler is wood flour.<sup>78</sup> Pieces pressed from wood-flour-filled phenolic resins can be made very accurately. The articles come from well-made molds with a high polish, have a higher dielectric strength than those made using asbestos and can be used at temperatures up to 120°C. Insulating pieces made from wood flour and phenol-aldehyde resins have been extensively used on automobile lighting and ignition systems, for lamp sockets, telephone parts and oil-immersed transformer insulators. Syono<sup>79</sup> states that articles which contain new wood cellulose retain a lacquer firmly. The addition of 0.5 part of pine tar to a mixture of 4 parts of phenolic resin, 3 parts of wood flour and 6 parts of powdered charcoal is said by Omansky<sup>80</sup> to produce a composition which flows easily in the mold and so gives accurate moldings.

Short cordage fibers, e.g., hemp and sisal, have also been suggested as fillers.<sup>81</sup> For example, a mixture of phenol-formaldehyde resol (700 parts), chopped manila hemp (600 parts), hexamethylenetetramine (227 parts of a 35.7 per cent alcoholic solution), methylated spirit (53 parts), aluminum stearate (24 parts) and nigrosine (28 parts) was dried at 60°C., ground and molded at 340°C. for 4 min. at 2000 pounds per square inch pressure. Herper<sup>82</sup> reports that exposing chips of wood or sawdust to a steam pressure of 58 kg. per sq. cm. for 4-5 sec. and suddenly releasing the pressure disintegrates the cellulosic material into fibers which can then be bound together with a phenol-formaldehyde resin. The product is light and has a tensile strength of 280-365 kg. per sq. cm.<sup>83</sup> A more thorough impregnation of fiber is obtained, according to Mellanoff,<sup>84</sup> if a condensation product of phenol, an alkaline extract of peat and formaldehyde is used as the binder.

The interspersing of a binder among long fibers is difficult by the methods previously mentioned. This is because the fibrous material mats together and

prevents uniform admixture of dry resin, and in the wet method of operation a lumpy product is obtained which must be ground, with resultant destruction of the fiber length. Kempton<sup>88</sup> stated that this difficulty could be overcome by impregnation of cloth, which after drying was chopped, shredded or ground to a loose fluffy mass of long fibers. Chamberlin<sup>89</sup> suggested that the impregnated fabric be cut into pieces and not shredded. In this way impact molding material<sup>90</sup> is made and bridges the gap between the usual molding compositions and the laminated (see Fig. 76). Like the former it is shaped in a mold and does not require machining, whereas like the latter it possesses a high impact strength (30 foot-pounds per inch square is possible as compared to 3.5 for wood-flour-filled). The strongest impact material requires about 5000 pounds per square inch to shape it but, nevertheless, it has found use in the manufacture of gears,<sup>91</sup> handles for tools, pump rotors and other articles which require considerable resistance to shock.<sup>92</sup>

When the usual organic fillers are employed, a considerable amount of resin is used in saturating the fibers. According to Hurst,<sup>93</sup> this assumed loss of binding material can be diminished by using cottonseed hulls. Thus, a mixture of 78 parts of cottonseed hulls, 20 parts of phenolic resin and 2 parts of dye molded satisfactorily at a pressure of 800 pounds per square inch and a temperature of 150°C.

A number of other organic fillers have been suggested. Ground phenol-resin

scrap is stated to give a uniform molding.<sup>91</sup> Ebonite,<sup>92</sup> sulphite waste,<sup>93</sup> ground cork,<sup>94</sup> hydrocellulose,<sup>95</sup> cellulose acetate<sup>96</sup> and cellulosic materials which had previously been treated with an oxidizing agent<sup>97</sup> have all been mentioned. Vegetable ivory bound with the product of permanganate oxidation of a phenol-formaldehyde resin has been used as a heat-insulating material for handles of cooking vessels.<sup>98</sup> Bormans<sup>99</sup> molded billiard balls from a phenolic resin filled with ivory scrap. The incorporation of soap as a lubricant in phonograph records of the phenol type has been suggested by Whyte.<sup>100</sup>

### MOLDING OF PHENOLIC RESINS

The molds<sup>101</sup> employed must withstand working pressures of over 1000 pounds per square inch and, in order to permit the temperature to be increased and decreased as rapidly as possible, they must contain a minimum of metal. The result is that the molds are usually made of a good grade of hardened steel. If the finished article is to have a smooth surface, the mold is highly polished, chromium plating being occasionally employed. Further, the molds have to be designed with sufficient head capacity to accommodate the molding composition which often occupies 3-4 times the volume of the finished piece. Hydraulic presses are employed which have capacities ranging from 5 tons upward and platens heated by steam, gas or electricity. The molds are heated either directly or by conduction from the platens.

The charge of powder is placed in the mold while the latter is at a temperature of about 90°C. The filled mold is placed immediately in the press, the platens of which are at 150-250°C. depending on the mixture used.<sup>102</sup> The press is closed and a pressure of 2000-3000 pounds per square inch is applied. The time required before the molded article may be removed depends on the molding powder and on the size and shape of the object. This period has been steadily decreased and for small pieces 0.5-1.0 minute is approximately the present requirement, whereas larger bodies may take 5-10 minutes. At one time, the moldings were finally baked in an oven to complete the condensation, remove any water formed in the reaction and to increase the dielectric strength.<sup>103</sup> Another former custom was to refrain from removing the article until the temperature

<sup>103</sup> G. L. Peakes (U. S. P. 1,602,249, Oct. 5, 1926, to Bakelite Corp.; *Chem. Abs.*, 1926, 20, 3796. British P. 275,011, 1926; *Brit. Chem. Abs. B*, 1927, 756) mentions heating at 125-135°C. for 70-80 hours, increasing the dielectric strength in some cases 70-80 per cent.

had been reduced to 95°C. Both of these practices have to a great extent been eliminated by the use of improved molding powders.

Some investigators have employed condensation products which were no longer truly fusible, but which softened enough at an elevated temperature to enable molding to take place. Aylsworth prepared phonograph records<sup>104</sup> and printing plates<sup>105</sup> from blanks which had previously been baked until almost complete hardening had taken place. Such blanks could be removed more rapidly from the expensive record mold than could those made using fusible compositions. It has been further stated that adhesion to the mold and blemishes due to the evolution of gases do not appear when relatively infusible condensation products are used.<sup>106</sup> Die pressing has been employed as a means of making troughs from sheets of phenolic resin in the C stage.<sup>107</sup>

Hollow balls containing compressed air have been made by Aylsworth and Smith<sup>108</sup> through welding together two hemispherical shells of partially reacted resin. The top half of the ball was placed in the plunger of a press which, as it moved downward, drove the enclosed air into the center. Hollow cylinders have been produced by using rotating molds, centrifugal force holding the contents in place during hardening.<sup>109</sup> Novotny<sup>110</sup> inserted pieces of solid carbon dioxide within the mass of material to be molded. As the temperature was raised, the solid volatilized, driving the plastic composition to the walls of the mold and forming a hollow object. Since very reactive resins can be controlled at the temperature of "dry ice" the addition of the latter was stated to enable the molding time to be cut down.<sup>111</sup> Stream-line tail pieces for airplane motor-generator sets have been formed by compacting paper pulp around a core, drying and impregnating with phenolic condensation products. The latter were finally cured under heat and pressure.<sup>112</sup>

The molding of dental plates differs from that of most articles in that a large number of identical objects is not required. Therefore, methods have been devised for using plaster of Paris molds which can be economically prepared. For example, porcelain teeth<sup>113</sup> are inserted in a denture made of wax. This is then surrounded with plaster of Paris and the wax is melted out leaving the teeth *in situ*.<sup>114</sup> The mold is painted with linseed oil to keep the molding from sticking to the plaster and the phenolic resin is added in the plastic state. The two halves of the mold are clamped together and heated in an autoclave (containing methylated spirits) to 121-149°C.<sup>115</sup> The finished article can be filed, sandpapered

Abs.*, 1928, 22, 2254) suggests coating the teeth with a yielding material to prevent breakage. See also H. J. Grange and S. W. Wilding, U. S. P. 1,669,557, May 15, 1928; *Chem. Abs.*, 1928, 22, 2446. British P. 258,674, 1925, to Amalgamated Dental Co., Ltd.; *Chem. Abs.*, 1927, 21, 3109.

<sup>115</sup> E. Wieland (U. S. P. 1,639,475, Aug. 16, 1927; *Chem. Abs.*, 1927, 21, 3276) suggested that the temperature be raised slowly to not above 80°C.

and polished.<sup>116</sup> It was also suggested that a similar procedure could be used to face ebonite dentures with a phenol-aldehyde resin.<sup>117</sup> Noyes<sup>118</sup> reinforced dental plates molded from phenolic resins with strips of fabric.

Since the mold in which a denture is formed need not be used again, Mombach<sup>119</sup> recommended that a metal powder be added to the plaster. When the molding was to be removed, the investment could be treated with acid, liberating hydrogen and decomposing the mold. In this way, the shaped structure could be freed. Lebach and Wirth<sup>120</sup> state that articles can be readily separated from metal molds providing the latter are first coated with a celluloid lacquer. If flat objects are being formed, newsprint impregnated with sodium bisulphate can be used. The celluloid and the impregnated paper are both destroyed at the temperature at which the resin is plastic.

In case the condensation of the phenol and the aldehyde is allowed to go too far, the product may still be partially thermoplastic, but not enough to give a good molding. Weber<sup>121</sup> has described such a resin which was made by refluxing 100 parts of phenol, 100 parts of formaldehyde (40 per cent solution) and 12.5 parts of concentrated ammonia until the product was a rubbery semi-solid mass. The aqueous solution was separated from the resulting resin, the latter was allowed to cool and was then crushed to a fine powder. On molding at 160°C., the full 1000 pounds pressure could be applied within 30 seconds of closing the mold. At the end of 5 minutes' time the article was removed and found to be opaque and to have only a fair surface. Weber found, however, that the addition of hexamethylenetetramine-triphenol in the ratio of 2 parts to 10 caused the overcured resin to flow easily in the mold, giving a translucent article with a good surface. The hexamethylenetetramine-triphenol was prepared by refluxing 48 parts of hexamethylenetetramine with 94 parts of phenol in a solvent composed of 60 parts of ethyl alcohol and 40 parts of water. On cooling the solution, the compound crystallized out. A second crop of crystals was obtained by concentrating the mother liquor. The product could be purified by recrystallization from hot alcohol. The use of chlorinated naphthalene and chlorinated phenols as solid solvents assisting in the molding of phenolic resins was early suggested by Aylsworth;<sup>122</sup> and benzyl alcohol,<sup>123</sup> naphthalene, anthracene and cumarone resin<sup>124</sup> have also been proposed.

A loud-speaker diaphragm has been made by hot pressing at about 800 kg per sq. cm. a mixture of solid polymer of formaldehyde and powdered phenol.<sup>125</sup> Burmeister<sup>126</sup> reports that, using resorcinol in this operation, 2-5 minutes at 120-125°C. is sufficient time for most articles.

A number of investigators have suggested that metal reinforcements be included within the phenol-aldehyde molding to increase its strength. Thus, Layman<sup>127</sup> made handles for various articles by shaping the resin about a wire which carried at each end devices for attaching to the body. Wires have also been

ton<sup>146</sup> proposed making a bearing for chromium-plated steel shafts from hardened phenol-formaldehyde resins faced with glass.

**Castable Resins.** The materials made by the early investigators of the phenolic resins left much to be desired in the matter of color and what is called tooling or machining. Therefore, much work was done in order to secure a condensation product that would not change in color with time and that could be machined or cut with the tools that were satisfactory on horn, vegetable ivory and related raw materials. The production of an article capable of being worked on a lathe or automatic screw-machine was fraught with difficulties because of the inherent brittleness and hardness of the resins. So great has been the progress in this direction that today we have a group of resins which are known as the turnery stock and which are available in a wide range of colors and shades. Such articles as chess pieces, checker men, buttons, bracelets, anklets, bases for lamps, door knobs, automobile gear-shift knobs and beads are made in a considerable annual tonnage. One advantage of casting is that it is the only recognized method which permits of the preparation of transparent objects from phenolic condensation products. In hot molding, cloudy products result due partly to incomplete fusion of the particles composing the powder.<sup>147</sup>

Even with casting, transparency is an elusive property. Absolute control during the condensing operation is most difficult; and, although a seeming uniformity is obtained by mixing batches, it was and is a great problem to make light-colored resins. Removing water during or after the preliminary condensation stage is also a serious obstacle and it is often necessary to check the reaction by dilution with organic solvents when dehydration nears completion. This frequently brings about incomplete reaction, and in consequence uncombined reagents are present in the finished product. Chief among these are water, alkali catalyst, phenol and aldehyde, all of which are to a degree destructive of transparency and usually render the material worthless for casting glass-clear masses.

A number of different means have been employed to obtain translucent and tough bodies. For example, condensation in the presence of salicylic acid followed by neutralization with a volatile amine and distillation *in vacuo* has been suggested.<sup>148</sup> Wennagel<sup>149</sup> proposed to use alkali soaps in proportions greater than one-fifth the molecular equivalent of the phenol as condensing agents. Deutsch and Thorn carried the reaction out in the presence of sodium carbonate and added salts of boric<sup>150</sup> or phosphoric acid<sup>151</sup> to render harmless the impurities which discolored the product. Acidification with acetic acid was stated to make the clarification more permanent. The same investigators report that, if salts of aromatic acids are added, the removal of water need not be as complete as it must otherwise be in order to obtain transparent resins.<sup>152</sup> The addition of sodium glycerate to toughen the product was advocated by Heinemann.<sup>153</sup>

The material known as "Catalin"<sup>154</sup> is of the cast phenol-formaldehyde type.

Pantke<sup>156</sup> has prepared clear masses in accordance with the following general procedure:

Phenol is mixed with commercial formaldehyde, and either caustic potash or soda is used as a catalyst. Extreme care is taken to select very pure raw materials if light shades are to be produced. The mixture is heated in an aluminum or nickel vessel under non-refluxing conditions at a relatively low temperature (not in excess of 80°C.) until water separates. Then the water is removed under vacuum and lactic acid<sup>156</sup> (U. S. P. quality) is added together with a small amount of glycerol.<sup>157</sup> The latter serves as a plasticizer as well as a modifier. Further heating at a low temperature carries the resinification to the desired point, as evidenced by drawing a sample and dropping a small portion into a beaker of water at 15°C. When it chills to a pasty mass just kneadable between the fingers, the resin is ready for casting into molds, which have been previously made by dipping hard steel arbors into molten lead (an antimonial lead) and then withdrawing the arbor by a slight shock. These molds are kept warm and when resin and mold are in proper condition the former is withdrawn from the kettle in hand-dippers and poured into the molds which have previously been racked on a truck. Extreme care is used in pouring in order that air bubbles are not left in the material. The truck is now wheeled into heated chambers (erroneously called "vulcanizers") and the casting is allowed to cure. After 2 or 3 days depending on the desired hardness, the truck is removed and the resin is punched out of the molds with air-hammers. The lead molds are scrapped and remelted.

The above procedure yields a nearly colorless resin capable of being machined with ordinary tools. It can be sanded, polished and in general compares to brass and the hard woods in workability.<sup>158</sup> Variations are accomplished by leaving in a percentage of water, addition of pigments, dyestuffs or inert fillers. The simulation of precious stones that is possible with this material is quite remarkable.

A number of modifications of the general procedure given above have been proposed. Pollak and Ostersetzer<sup>159</sup> stated that care should be taken lest the resin separate from the water. According to them, it was desirable to have the product in the form of a gel. A large proportion (about 2½ mols to 1 of phenol) of formaldehyde was also used.<sup>160</sup> If transparent resins were to be made, acids which would give soluble salts with the bases used in the initial condensation were employed.<sup>161</sup> On the other hand, Loos<sup>162</sup> produced cloudy effects resembling marble by precipitating potassium acid tartrate throughout the mass. The addition of phenol in several portions during the course of the reaction has been reported to assist in keeping the resin in solution<sup>163</sup> and to result in a body which does not contain any free formaldehyde.<sup>164</sup> The latter end can also be attained by adding

<sup>156</sup> O. Pantke, U. S. P. 1,909,786, May 16, 1933, to Catalin Corp. of Am.; *Chem. Abs.*, 1933, 27, 3837. See also W. Peterson and E. V. Clark, British P. 179,586, 1921; *Chem. Abs.*, 1922, 16, 3531.

urea at the end of the condensation.<sup>165</sup> Jäger<sup>166</sup> employed sodium stearate and sodium sebacate as initial condensing agents. He also states that colorless products are obtained by adding such salts of strong organic bases as piperidine pentamethylenedithiocarbamate to a phenol-formaldehyde-ammonia reaction-mixture before or after condensation.<sup>167</sup>

In accordance with the methods outlined, artificial jewelry, handles for knives and umbrellas, cabinets, high-tension insulators<sup>168</sup> and a large number of similar objects have been manufactured. The purification of clear transparent resins has also attracted attention. Surfaces which have become matt or discolored by exposure to light or air may be rendered glossy by treatment with nitrogen-free carbocyclic or heterocyclic liquids such as dioxane, cyclohexanone or cyclohexanol.<sup>169</sup>

A proposed application of such transparent bodies is the construction of models to be used in photo-elasticity tests.<sup>170</sup> When the models are viewed with polarized light, they appear to be differently colored depending on the degree of stress. In this way, quantitative measurements of the distribution of load in such structures as the frame of a dirigible may be made. A viewing-polariscope for selection of material free from initial strains may be made as follows. It can be used of course on any transparent object (lamp shades, castings, films or composite sheets of safety glass) as well as on material for model construction.

A suitable light source for a viewing-polariscope may be a board about a foot square on which a number of electric light bulbs have been mounted. Directly below this is a sheet of glass having both sides sanded or a ground glass surface. This acts as a source of diffused light so that the filaments of the bulbs are not really visible through it. A piece of black glass about 12 inches x 18 inches is set directly below the ground glass surface so that it is inclined to the vertical rays of light from the ground glass surface at an angle of about 45° and arranged to reflect the light horizontally toward the left. This polarizes the light coming from the ground glass surface by reflection in a given plane.

A second piece of black glass is then placed so that it is at an angle of 45° to the light reflected from the first black reflecting surface and so that the reflected light will come directly out horizontally toward the observer and at right angles to the rays coming from the first reflecting surface. Two black sheets of laminated phenolic material will work very nicely as these two reflecting surfaces instead of the black glass. Highly polished metal surfaces would also be satisfactory, but ordinary mirrors with silvered surfaces cannot be used on account of reflection from both the front and back of the glass. The reflecting surfaces would function best if they were arranged so as to be at the critical angle with respect to the incident light beam, but the 45° arrangement will function quite satisfactorily and is much easier to set up and use.

The sheet of material to be studied is placed with its plane at right angles to the light beam upon its reflection from the first reflecting surface and before the light falls upon the second reflecting surface. The observer looks into the second reflecting surface, getting in the line of the reflected rays from that surface. By rotating the sheet of material with its plane perpendicular to the incident polarized rays around the line of the incident rays as an axis, the positions of strains in the sheet can be readily located as they will cause colored bands to appear during the rotation.

It has been stated above that accurate shapes cannot be made by casting. However, in some cases where hot molding is impracticable or where accuracy of

detail is not needed,<sup>171</sup> casting has been employed as a means of shaping. Thus, Wirth<sup>172</sup> formed pasty masses of phenolic resins filled with acid-resistant materials, e.g., asbestos, in open molds similar to those used with concrete. Hardening was then effected by applying heat. Objects manufactured in this way were somewhat porous and the surface was covered with a dense crust. The latter had to be removed by grinding or sand-blasting before the temperature was raised above 130°C. or blistering would occur. The articles were finally heated to 200°C. or more. With large pieces, the heating took at least 30-70 hours. Cylinders measuring 2 m. high, 2 m. in diameter and 4 cm. in thickness and other types of castings have been made in this way.<sup>173</sup>

Tubes may be pressed from phenol-formaldehyde resins both in the cold<sup>174</sup> and at elevated temperatures.<sup>175</sup> In the former case, the hardening of the resin is accomplished by passing hot air through the tube, producing a dense inner surface. Rods can be made in similar manner.

A phenolic composition which can be cold molded has been prepared by Ellis.<sup>176</sup> One hundred parts of o-cresol, 50<sup>177</sup> parts of paraform and 4 parts of aqueous caustic soda solution (30 per cent) were heated for 3½ hours on a vigorously boiling water bath. A reddish turbid solid resin was obtained which was soft at first but on standing a few hours became brittle. Asbestos fiber (75 parts) was impregnated with an acetone solution of the resin (20 parts) and tung oil (2 parts). The mass was spread in thin layers and dried at 70°C. for about 1 hour. It could then be shaped in a press at a pressure of 15,000 pounds per square inch and hardened by baking in an oven. The temperature was raised slowly from 60°C. to above 100°C. and then more rapidly to 140°C. Disks made in this way had a breaking-strength of 7 pounds per mm. of thickness.

Ariente and Flick<sup>177</sup> applied drops of liquid phenolic resins to fabric and completed the condensation by heating. It is stated that this method of decorating is better than similar ones used previously in that the globules<sup>178</sup> were neither soluble nor thermoplastic. Articles can also be made by electrodepositing the resin from aqueous dispersion on a mold surrounding the anode, followed, as in the other cases where the shaping is done in the cold, by baking.<sup>179</sup>

#### LAMINATED MATERIALS

In the electrical field, it was formerly common practice to coat paper with varnish or solutions of natural resins and to compact the sheets into a solid block by hot pressing. Shellac, copal and other natural resins have all been used. Copal and shellac yield pressboard which possesses good mechanical and electrical properties when cold but which softens when heated to 70-90°C. Therefore, the

<sup>171</sup> Cf. the manufacture of grinding wheels by shaping abrasive grains coated with a resin followed by baking while still in the mold. A. J. Doermann, U. S. mechanical and (to a large extent) the electrical strength are lost when a temperature of 80°C. is reached. Such temperature conditions are of course not unlikely under service conditions in many types of electrical apparatus. As soon as the manufacture of phenol-formaldehyde resins became developed commercially, they were employed for the manufacture of laminated pressboard.<sup>120</sup> The mechanical strength of such pressboard does not decrease with increase in temperature to nearly as great an extent as does that of material made from natural resins.

Phenol-formaldehyde resins have also found wide use as a coating or impregnant for canvas and fiber. As a dielectric, dry fiber is ideal in many ways, but its tendency to absorb water affects its properties. Impregnating and binding together the fibers with a resin greatly reduces this tendency.<sup>121</sup> However, the reaction taking place when phenol-formaldehyde resins undergo hardening develops water and the presence of this reduces the dielectric strength. Great progress has, however, been made in the production of such pressboard and it is now being used for purposes where only the best insulators can be employed, e.g., wireless apparatus and electric railway track insulation.<sup>122</sup> Impregnated canvas is used more for mechanical than electrical purposes. It finds employment in the manufacture of noiseless gears, airplane propellers and in numerous other ways.<sup>123</sup>

The usual method of impregnating fabric is to use a solution of resin (in the A stage) through which a web of the material is passed continuously. The varnish-laden sheet then goes to a drier (usually of the tower type) where the solvent is evaporated.<sup>124</sup> If 1.5-3 per cent (based on the solid content) of tung oil is added to the solution, the resulting film will be more coherent.<sup>125</sup> A further modification involves washing the partially dried fabric with water or dilute alkali to effect removal of any compounds which produce objectionable odors.<sup>126</sup> However, other means similar to those which were mentioned for preparing molding compositions can be employed. That is, a liquid condensation product may

<sup>120</sup> Cf. the use of phenolic condensation products as adhesives in uniting wood and paper. R. W. Seabury, U. S. P. 1,625,749, April 19, 1927; *Chem. Abs.*, 1927, 21, 2054.

will be more rapid. However, up to 50 per cent of this phenol may be replaced without unduly prolonging the process.<sup>191</sup>

There are three principal types of phenol-formaldehyde laminated sheets depending on the kind of fabric used in their manufacture. Paper is commonly used for electrical insulation,<sup>192</sup> but if greater strength is required linen and canvas are employed. Where high insulation value and resistance to moisture are of special importance, rag paper with about 50 per cent impregnation has been suggested. Hoey<sup>188</sup> proposed to use sheets which were alternately impervious and absorbent. Graduation in the dielectric constants of multiple cable insulation has

been obtained by impregnating with solutions of different strengths.<sup>194</sup> Kraft paper<sup>195</sup> produces a stock which is resilient enough to be fashioned by punching. Further uses to which laminated paper has been applied are the manufacture of phonograph records<sup>196</sup> and damping-members for telephone diaphragms.<sup>197</sup> McIntosh<sup>198</sup> stated that a hard, tough waterproof product could be obtained from vulcanized fiber stock. A proposed wood substitute was built up from layers of pulp board.<sup>199</sup>

Phenol-formaldehyde linen-laminated sheet, because of the closely woven and uniform structure of the fabric layers, is especially adapted to the preparation of punched parts and the cutting of gears of small face dimension. It is stronger than paper and gives clean-cut, smooth edges. Canvas as a reinforcing material results in a sheet of maximum strength which can be used for the large gears

FIG 79—A Bakelite Laminated Gear in an Automobile Timing Mechanism.

found in industrial machinery.<sup>200</sup> Such gears are more silent than metal ones and have demonstrated their ability to outlast metal in surroundings where corrosive solutions and abrasive dusts are encountered. In use, the laminated gears are arranged meshing with metal ones of at least equal width of face (see Fig. 79).

Conrad<sup>201</sup> simply cut gears from laminated stock. On the other hand, Bastian<sup>202</sup> punched the required shapes from impregnated sheets and then molded them together. The addition of graphite to self-lubricating gears has already been mentioned.<sup>203</sup> Another method impregnates the fabric with a non-drying oil previous to imbedding in the synthetic resin.<sup>204</sup> Metallic centers may also be included in

both gears<sup>205</sup> and abrasive wheels.<sup>206</sup> Sprenger<sup>207</sup> suggested that the teeth be formed of spirally wound cloth. Such a procedure would eliminate the waste inherent in cutting circular objects.<sup>208</sup>

Airplane propellers possessing a number of useful properties, including uniformity of texture, elasticity and absence of warping, have been made from laminated duck. Five or six sheets were formed together into a board, which was then shaped with a saw and finally molded under pressure at 175°C.<sup>209</sup> Woven fabrics have also been suggested for use in the manufacture of acoustic diaphragms,<sup>210</sup> billiard balls,<sup>211</sup> trays,<sup>212</sup> rayon-spinning pots<sup>213</sup> (see Fig. 80) and acid-proof receptacles.<sup>214</sup>

Stevenson<sup>215</sup> has recommended that the laminated sheet be built up of untreated cloth, then stitched or quilted together and finally impregnated. According to him, this procedure eliminated air pockets between the sheets and so resulted in a stronger body. The preparation of a non-laminated article by treating a specially woven fabric with a phenol-formaldehyde varnish has also been proposed.<sup>216</sup>

Asbestos sheets<sup>217</sup> have been used to make valve disks, gaskets and brake blocks.<sup>218</sup> According to Achtmeyer,<sup>219</sup> the employment of asbestos webbing in clutch facings is inconvenient since it tends to pucker when bent in a circle. On the other hand, sheets obtained by laying fibrous material in a paper machine are liable to break parallel with the fibers. The latter difficulty can be avoided by orienting the superimposed laminae at right angles to each other. Robertson<sup>220</sup> built up a friction material for use in brakes and clutches from alternate layers of asbestos fabric and granulated cork. Superposition of paper and layers of powdered glass is said to produce a body which is relatively bullet-proof.<sup>221</sup> Another form of laminated sheet has been made from flakes of mica bound with a phenol-urea-formalde-

hyde varnish.<sup>222</sup> McIntosh<sup>223</sup> proposed to make noiseless gears from layers of leather impregnated with a phenolic resin.

Wood-base Micarta is produced by saturating plywood and compacting a number of plies under a pressure of 1500 pounds per square inch and at a temperature of 140°C. One and a half hours is required for each inch of thickness and the material is allowed to cool to room temperature before removing from the press.<sup>224</sup> Oil-switch lift-rods constructed of such material are said by Read<sup>225</sup> to have breaking strengths superior to those made from natural materials.

**Rods and Tubes.** The usual method of making rods of laminated material is to machine them from sheet stock. Frederick<sup>226</sup> suggested that, if the condensation of the resin has not been carried to its final stage, rods can be molded from strips cut from a sheet. A method of making tubes is to wind laminated sheets around a core, remove the core, and cure the objects in a heated mold. Tubes are known as rolled or molded depending on whether heat and pressure are applied

Courtesy Bakelite Corp.

FIG. 80.—Fuselage and Wings of this Plane Are Made of Laminated Wood Bonded with a Phenolic Resin.

during the rolling<sup>227</sup> or afterwards in steel molds. In the latter case, the pressure may be applied either axially<sup>228</sup> or from the sides.<sup>229</sup> Kempton<sup>230</sup> has described a type of expanding mandrel which will apply the pressure from the inside of the tube. Standard sizes of such tubes include inside diameters of 3/16 inch to 72 inches and wall-thicknesses of 1/32 inch to 1½ inches.

In one method of making insulating tubes for coils of wire, a sheet of impregnated material is folded into a series of sharp parallel ribs and then cured in a mold of the same shape.<sup>251</sup> Tubes of desired size are made by cutting the sheets in proper widths and bending them into cylinders. The ribs give as little contact as possible between the tube and the wire wound on it.

**Veneers.** In some cases, it has been desirable to prepare articles in which the surfaces are different in composition from the body. Phenol-aldehyde insulators char when a spark passes over their surface with a resultant loss in resistance. Such is not the case with alkyd resins,<sup>252</sup> and so Barringer<sup>253</sup> has coated both moldings and laminated sheets with the latter substances to minimize the effect. Barrier rings for alternating-current motors have been made from a sheet of impregnated asbestos fabric between two rings of a wood-flour-filled molding composition. The former resisted flash-overs although the latter had a larger dielectric strength.<sup>254</sup> Valve disks having outside layers of asbestos fabric covering an inside mass of asbestos fibers have also been prepared.<sup>255</sup> Whitehouse<sup>256</sup> faced buttons of phenolic resin with celluloid. Nitrocellulose (additionally waterproofed by inclusion of a wax) and phenol-aldehyde condensation products were cast together on a cellulose acetate film<sup>257</sup> to form a duplex waterproof foil. The use of phenolic-resin impregnated veneers on a shellac-bonded sheet is stated by Cox<sup>258</sup> to avoid certain difficulties laid to the adhesive character of the shellac.

To cause cellulose-acetate-impregnated sheets to adhere to fibrous sheets impregnated with phenol resin, Worrell and Gruber<sup>259a</sup> employed a middle sheet impregnated with a mixture of phenol resin and cellulose acetate.

Phonograph records<sup>260</sup> were originally made from shellac and for many years this was the principal substance used. Its hardness and toughness and the simplicity of molding records containing it presented a hard problem to the synthetic-resin chemist seeking to produce a substitute. Aylsworth<sup>260</sup> devised a number of means of preparing a smooth hard layer of pure phenol-formaldehyde condensation product or one in which there was only a small quantity of filler and of affixing it on a supporting blank containing a larger amount of diluent. Usually the resin in the surface was relatively infusible, but contained some plasticizing agent.<sup>261</sup> The same investigator suggested that the body of a cylindrical record

<sup>261</sup> Several plasticizers are mentioned above in connection with the work of Weber on hexamethylenetetramine-triphenol. See also Chapter 20 on modified phenol-formaldehyde resins.

be made of a composition which contained an excess of polymerized formaldehyde. On molding, this would be evolved in gaseous form producing a porous structure.<sup>242</sup>

Sound records were made by Novotny<sup>243</sup> from a fusible phenol-acetaldehyde resin. The condensation product was dissolved in alcohol to form a thin solution and hexamethylenetetramine was added. Sheets of fiber were impregnated and subsequently heated to remove solvents and partially react the resin, thus largely preventing side-flow during hot pressing. A plurality of sheets were cemented together with the resin solution and subjected to heavy pressure to insure firm adhesion. The product was coated with a thick paint composed of barium sulphate<sup>244</sup> and resin solution. Such blanks were heated at 120°C. for about 1 hour, coated a second time with the resin, dried to remove solvent and hot pressed in a record mold. Edison<sup>245</sup> recommended that a blank be coated with several layers of varnish instead of the two which previous workers had used.

A related material which can be employed for printing surfaces and stereotype matrices is made from a fibrous sheet which has been impregnated with a phenol-aldehyde condensation product. The sheet is heated until it is dry and crisp and the surfaces are then coated with several layers of phenol resin. Each layer is set by heating before the next is applied. The filler in the coatings is lampblack and the quantity used decreases progressively towards the surface.<sup>246</sup>

Playing cards have been similarly made by covering both sides of an impregnated linen sheet with phenol-formaldehyde resins. Such cards are reported as durable and possessing the requisite flexibility and finish.<sup>247</sup> A composite plate having veneers of impregnated parchmented paper and a center of plain parchmented stock is said to be less expensive than one uniformly saturated.<sup>248</sup> Loetscher<sup>249</sup> coated fiber board with a phenol-formaldehyde varnish and covered both sides with impregnated sheets of kraft paper. On the top surface a layer of powdered quartz coated with phenol resin was spread and the whole body was compressed under 50-100 pounds per square inch at a temperature high enough to fuse the binder. The finished product was used as a floor covering.

Table tops and similar articles of furniture were also made by pressing impregnated wood veneers around fibrous cores.<sup>250</sup> Such veneers are said not to be scorched by contact with matches or cigarettes.<sup>251</sup> Plywood reinforced with cloth can be molded over irregular surfaces.<sup>252</sup> Fire-resisting paneling having one or more

Thin sheets of metal,<sup>260</sup> onion-skin paper<sup>261</sup> or regenerated cellulose<sup>262</sup> have been used to face laminated stereotype matrices. Swan and Higgins<sup>263</sup> state that the insertion of a layer of vulcanized rubber cuts down the sound-transmission and increases the flexibility. Such material has been suggested for airplane cabins and cafeteria table tops. A backing of rubber has been used on printing plates of phenolic resin to minimize the danger of breaking.<sup>264</sup> Freeman and Catt<sup>265</sup> joined the fabric jacket of a rubber tube to the interior with phenolic cement. Asbestos sheets containing barium sulphate and bound with rubber or "Thiolite"<sup>266</sup> have been used as impervious layers on the outside of an asbestos-metal fabric gasket impregnated with a phenol condensation product.<sup>267</sup>

**Adhesives for Metals and Glass.** Phenolic resins have also been employed as adhesives for such substances as metals and glass which, of course, differ from the fabrics discussed above in that they possess relatively impervious structures. Investigations carried out by the Adhesive Research Committee<sup>268</sup> demonstrate that when saligenin is heated at about 130°C., the strength of the resulting adhesive increases progressively. After one hour, a phenol-formaldehyde type resin was obtained which was almost 7 times stronger than the original compound. The increase in strength was attributed to the disorderly structure which was assumed to be formed in resinification. A cement has been suggested in which neutral metallic oxides, aromatic sulphonyl chlorides or alkyl sulphates were added to a liquid phenol-formaldehyde condensation product to catalyze the hardening.<sup>269</sup> A resin for cementing glass and metals has been prepared by heating benzoic or cinnamic acid with glycerol, phenol and formaldehyde. The reaction product was dehydrated by vacuum distillation.<sup>270</sup> Warming a mixture of 40 parts of phenol, 100 parts of formaldehyde solution and 1.2 parts of sodium hydroxide for about 2.5 hours at 62°C. followed by treating with 3.3 parts of lactic acid and keeping at 60°C. until the mass is syrupy is said to produce a waterproof adhesive.<sup>271</sup> Aylsworth<sup>272</sup> dissolved 100 parts of fusible phenol resin in 100 parts of alcohol containing 20-50 parts of a nonvolatile solvent (monochloronaphthalene, glycerol or castor oil). Seven to eleven parts of hexamethylenetetramine and 50-300 parts of finely divided filler were also added. The material was intended to be used in sealing the joints of metal pipes. Veneers of paper and wood have been joined under heat and pressure to metal with water-soluble phenolic condensation products.<sup>273</sup> In electrical condensers the adhesive acts as a dielectric also.<sup>274</sup>

On the other hand some lack of success is encountered in affixing large sheets of phenol-formaldehyde resin to metal plates. Due probably to the differences in thermal expansion the two layers separate in time. A number of rubber cements<sup>275</sup> have been proposed to obviate this difficulty. Another method fastens an intermediate sheet of felt to a steel backing with a low-melting alloy.<sup>276</sup> Loetscher<sup>277</sup> reports that interposing a layer of paper saturated with phenol-formaldehyde-carbohydrate resin will also prevent separation.<sup>278</sup>

Double window panes have been formed by placing two sheets of glass at a slight distance apart and interposing along their edges an elastic filler, the surface of which had been previously coated with a phenolic condensation product. The latter was subsequently fused by raising the temperature.<sup>279</sup> Safety glass is made by uniting sheets of cellulose nitrate or acetate to exterior layers of glass.<sup>280</sup> In one way of using phenol-formaldehyde adhesives, glass is first polished with emery. A thick solution of the resin in acetone or alcohol is spread on at 30-40°C. with a spatula, and the temperature is raised to 80°C. to drive off the solvent. The sheets are then laid on top of each other and united by heating under about 5 atmospheres pressure.<sup>281</sup> To save solvent a melted resin can also be used.<sup>282</sup> It has been suggested to omit the layer of cellulose ester, but such products have not proven entirely satisfactory since the inclusion of the ester greatly strengthens the material. Long<sup>283</sup> reports that the union between glass surfaces has, if the resin layer is thin enough, a greater tensile strength than the glass itself. A further proposal reinforces glass objects with exterior coatings of phenolic resins.<sup>284</sup> One disadvantage which such condensation products have and which limits their use in safety glass is the tendency to darken on exposure to light.

Unbreakable transparent sheets to be used as a substitute for glass have been made by uniting two layers of celluloid with phenol-aldehyde resins.<sup>285</sup> Another glass substitute consists of gauze coated with an amount of phenolic resin insufficient to close the reticulations<sup>286</sup> and then with cellulose acetate filling the openings.<sup>287</sup> Keay<sup>288</sup> proposed to use a cement made of sand, phenol-formaldehyde resin

and furfural to unite pulp-grinding stones. Porcelain insulators have been joined together by similar compositions.<sup>290</sup> Merritt<sup>290</sup> spread a dry powder of phenolic resin over a sheet of mineral board, placed a veneer on top and united the sheets by subjecting to heat and pressure.

### VARIOUS IMPREGNATED BODIES

Phenol-aldehyde condensation products are used as impregnants for wood, concrete, asbestos millboard and electrical coils. The products differ from those described under laminated materials in that the former are in nearly their final shape before impregnation. However, the resin serves in approximately the same ways, i.e., as a binder and to increase the resistance to water, chemicals and the weather. As with laminated materials and molding compositions, it has been proposed to prepare the impregnant *in situ*. Aylsworth<sup>291</sup> saturated the object to be indurated with a solution of hexamethylenetetramine, dried and then treated at 76-99°C. with a solution of a fusible phenolic resin. The body was finally heated to transform the impregnant into the infusible form. Another method of preparing the resin *in situ* employs aldehyde-ammonia in place of hexamethylenetetramine.<sup>292</sup> The use of furfural with a condensation product which liberates ammonia during transformation to the infusible state will prevent the formation of bubbles.<sup>293</sup>

Studies on the properties of impregnated wood have been made by Schmidt,<sup>294</sup> Brajnikoff<sup>295</sup> and Klinov.<sup>296</sup> It was noted that the tensile and compressive strengths parallel to the grain could be doubled and the amount of water absorbed after a month's soaking was decreased by about 95 per cent.<sup>297</sup> The natural color of the wood was changed very little and the material could be easily worked and machined. Beech wood was made practically impervious to steam and had its resistance toward various acids (80 per cent acetic, 36.9 per cent hydrochloric and concentrated phosphoric), 5 per cent sodium hydroxide solution and the halogens greatly improved. Methyl and ethyl alcohols, acetone, ether, benzene and benzine had no effect at room temperature whereas chloroform and hot (90°C.) transformer oil had a swelling action. Concentrated sulphuric and nitric acids and cold 20 per cent caustic potash solution were the only reagents which attacked the material seriously. Such impregnated wood has been suggested for flooring, furniture,<sup>298</sup> machine bearings,<sup>299</sup> battery-wells<sup>300</sup> and golf-club heads.<sup>301</sup>

with a liquid phenolic resin at 60-80°C. The latter was then hardened at 100-130°C. The addition of a phenol-aldehyde condensation product in alkaline solution to the mixing water of cement has also been suggested.<sup>303</sup> Silicate grinding wheels may be similarly strengthened by indurating with phenolic resins.<sup>304</sup> Howes<sup>305</sup> investigated the effect of continued heating on the electrical properties of field coils<sup>306</sup> impregnated with a phenol-formaldehyde condensation product. A continuous increase in resistance and decrease in power factor were noted. Except for mechanical deterioration, which was considerable at 150°C., the coils showed signs of lasting indefinitely.

Although asbestos sheets saturated with phenolic resins have been proposed as shields for the dies used in molding electrical insulators<sup>307</sup> and as spacers in heat-insulations,<sup>308</sup> a more important use has been as clutch facings and brake bands. According to Novak,<sup>309</sup> impregnation has the advantage over molding in that curved molds are not required since the treated strip can be shaped on a roll before hardening the resin. It has been suggested to use rosin along with the phenolic binder for the purpose of increasing friction. Thus, Fisher<sup>310</sup> used an alcoholic solution of soluble condensation product and rosin (not more than 10 per cent of the weight of the asbestos) to saturate asbestos rings which were then dried and heated to 150-200°C. Since both rosin and certain of the phenol-formaldehyde resins will dissolve in alkali, Novak<sup>311</sup> has employed alkaline solutions as impregnants. The saturated material was dipped into a bath of 10 per cent sulphuric acid to precipitate the binder and rosin. Castor oil has also been included to act both as a solvent during the impregnation and as an agent for increasing flexibility.<sup>312</sup> When the solvent used is a drying oil, it serves as an additional binder.<sup>313</sup> Frood<sup>314</sup> formed friction-elements, stair-treads, and soles and heels for shoes from fibrous materials held together with a mixture of rubber and dammar gum. He reports that a phenol-aldehyde condensation product can be included if desired.<sup>315</sup> Other asbestos objects have been made which were impregnated with both asphalt and phenolic resins. The material could be saturated first with the asphalt<sup>316</sup> or

with the synthetic binder<sup>317</sup> or the latter could be formed *in situ* (phenol included with the bituminous material and then treated with formaldehyde after the impregnation).<sup>318</sup>

### DECORATION OF MOLDED AND LAMINATED OBJECTS

A number of workers have attempted to prepare more attractive objects by various methods of decorating. One of the simplest is to mix molding powders of different colors. These will flow in the mold, resulting in a grained or mottled appearance.<sup>319</sup> Frederick<sup>320</sup> suggested that a similar effect could be obtained in laminated material by using differently colored sheets. Embossed designs have also been applied to partially cured articles and then hardened in place.<sup>321</sup> Carter<sup>322</sup>

FIG. 82.—  
Piling Sheets of Paper  
Impregnated with Phenolic Resin.

Courtesy Bakelite Corp.

proposed to form laminated sheets having a surface layer carrying a design. This was impregnated with a clear binder and backed with an opaque coating of titanium oxide or zinc sulphide. Carbon transfers and decalcomanias have been similarly applied to the surfaces of molded articles and then covered with a liquid resin which was finally hardened in place.<sup>323</sup> A thin imitation wood veneer was made by McIntosh<sup>324</sup> from an impregnated sheet of paper which had been laid on a thick body of fibrous material. After the binder had set, the sheet was removed with an adhering portion of fibrous material.

Several methods of coating molded articles with metals have been suggested. Eaton<sup>325</sup> sprinkled finely divided copper or aluminum over the surface of the mold. Powdered carbon has been added to a molding composition to make it electrically conductive. A coating of metal could then be electrodeposited on the finished molding.<sup>326</sup> Other processes form a thin film of an easily reduced metal salt on the surface. On reduction, the layer formed is conductive, permitting subsequent electroplating with additional metal.<sup>327</sup>

Petrov<sup>328</sup> reports that articles obtained from phenol-aldehyde condensation products can be colored or rendered resistant to attack by the atmosphere through immersing them in solutions of dyes and protective agents, e.g., quaiol, aminophenols, tannin, shellac and cellulose ethers. The dyes are fixed by treatment with dichromate solution. Another suggestion was to treat the articles with aqueous solutions of phenols or sulphonic acids before placing in the coloring bath.<sup>329</sup> The manufacture of artificial pearls has been attempted by Paiseau<sup>330</sup> through the use of shiny particles (obtained from fish scales or from swimming bladders) as fillers. Similar results are also stated to be obtained by using barium thiosulphate and various precipitates, e.g., fatty acids from soaps, uric acid from sodium urate, tin sulphate and cadmium iodide.<sup>331</sup> According to Parkert,<sup>332</sup> a more successful result is obtained if the decorative material is present in a layer and is covered with a number of thin coatings of celluloid and phenolic resin.

#### MISCELLANEOUS APPLICATIONS

The phenol-aldehyde condensation products are compatible with quite a number of other binders. The mixtures in some cases have found application since the properties differ from those of either ingredient.<sup>333</sup> Moss and Crutchfield<sup>334</sup> proposed to use an adhesive containing cellulose acetate and a urea-phenol-formaldehyde resin in making safety glass. According to Gardner,<sup>335</sup> an electrically insulating thread may be made by extruding an acetone solution of 5 g. of phenol-formaldehyde resin, 5 g. of shellac and 100 g. of cellulose acetate containing 10 g. of finely divided mica. If desired, viscose<sup>336</sup> can be employed in place of the ester. Films and filaments have also been formed from colloidal suspensions of phenol-formaldehyde condensation products containing dissolved alkyl celluloses.<sup>337</sup>

Rubber has been included in a phenol-aldehyde adhesive to join elastic sheets to

metal.<sup>338</sup> Trist<sup>339</sup> reports that a packing composed of textile material in a matrix of rubber can be treated so that it is resistant to oil, acid and alkali by immersing it in a mixture of solvents, one constituent of which softens the rubber and the other is a solvent for the resistant substance. Shellac and bitumen are used to give oil- and acid-resisting packings respectively. Synthetic resins of the phenol class can also be employed. The addition of a phenolic condensation product to a rubber-bound abrasive wheel is said to render the product less affected by heat changes.<sup>340</sup> Benjamin<sup>341</sup> states that a substitute for leather can be made from the reaction product of cresol and formaldehyde. He proposed the following composition: rubber (23.8 per cent), synthetic resin (2.6 per cent), sulphur (1.1 per cent), asbestos (6.1 per cent), mica (42 per cent), cotton shoddy (17.5 per cent), lamp-black (1.7 per cent) and litharge (5.2 per cent). Separators for electrical accumulators have been produced from diatomaceous earth held together with a binder consisting of rubber and a phenolic resin.<sup>342</sup>

Coleman and Groten<sup>343</sup> report that compositions which contain mixtures of drying oils, asphaltic material, copal and rapid-hardening plastics (phenol-formaldehyde) as binders can be removed from the mold after less time than can the usual types of hot-molding powder.<sup>344</sup> The articles are baked at a gradually rising temperature for 8-40 hours to complete the hardening. The products have a good polish and adequate strength. Sandpaper has been prepared using linseed oil to waterproof the backing and also as a component of the adhesive.<sup>345</sup> Laminated stock made from sheets of paper impregnated alternately with drying oils and phenolic resins are said to have considerable mechanical strength and elasticity.<sup>346</sup>

The condensation products which are obtained from the action of formaldehyde on phenols precipitate albuminoids, e.g., glue and gelatin, from their solutions. However, Arnot<sup>347</sup> reports that, if the glue is partially hydrolyzed before adding the condensation product, no coagulation takes place.

For example, 500 parts of 40 per cent formaldehyde were run into 1000 parts of dark cresylic acid (97 per cent) and then 20 parts of finely powdered bleaching powder were added. The temperature was held at 90°C. for about 30 minutes after which the mixture is allowed to stand for an hour. The oily layer was run while still hot into liquid glue. The latter was prepared by heating 1200 parts of ground hideglue, 24 parts of sodium bicarbonate and 2000 parts of water in an autoclave at 130°C. for 2.5-3 hours. The adhesive formed by mixing the two liquids is stated to be applicable

to the uniting of wood veneers. At a pressure of 300 pounds per square inch and a temperature of 110-120°C., the gluing was effected in 8-10 minutes.<sup>540</sup>

An adhesive of greater elasticity was obtained by adding rubber or factice<sup>541</sup> to the cresol before condensation. Impermeable plastic masses are said to result when dried blood is incorporated with phenol before or after the condensing with formaldehyde.<sup>542</sup> A suggested leather substitute consists of leather scrap bound together by a phenol-formaldehyde condensation product mixed with albumin or keratinous substances.<sup>543</sup> Jeschke<sup>544</sup> heated glue with glycerol and then added a phenolic resin and continued heating until a tough viscous mass resulted. This was proposed as a binder in linoleum.<sup>545</sup>

Shellac and Manila copal have been included in plastic compositions,<sup>546</sup> cements<sup>547</sup> and impregnants<sup>548</sup> prepared from phenol-formaldehyde condensation products. In each case, the toughness of the material was said to be increased. Field and Haslett<sup>549</sup> mixed equal parts of a solution of Canada balsam in xylene and a solution of glycerol-phenol-formaldehyde resin in 40 per cent aqueous alcohol. Both liquids were of the consistency of syrup. The mixture was suggested as an adhesive in making safety glass.

A composition containing abrasive grains, phenols, aldehydes, hardening agent and an alkyd resin produced *in situ* has been used by Novotny<sup>550</sup> in the production of grinding wheels. Layers of fabric impregnated with glycerol-phthalic-anhydride-type resins have been bonded into laminated sheets with phenolic condensation products.<sup>551</sup> Such material is stated to be applicable in making machine parts which are required to resist shock. The use of small proportions of chloronaphthalene waxes as plasticizers for the phenol type of resins has already been mentioned. Aylsworth employed larger proportions in producing fireproof roofing<sup>552</sup> and furniture polish.<sup>553</sup> The latter consisted of cresol-formaldehyde condensation product (40-55 parts), chloronaphthalene wax (75 parts), acetylene tetrachloride (55-65 parts) and benzene (80-120 parts). A bearing for high-speed machinery has been made from sericite schist and pulverized lead held together with wax and a phenolic binder.<sup>554</sup>

Since impregnations with solutions usually possess a more or less porous structure after the solvent has evaporated, it has been suggested that the pores be par-

<sup>540</sup> A similar product has been employed in the manufacture of sandpaper. C. Klungspor, U. S. P. 1,833,715, Nov. 24, 1931; *Chem. Abs.*, 1932, 26, 1088. British P. 293,232 and 302,430, 1927; *Chem. Abs.*, 1929, 23, 1524, 4316.

tially filled with sulphur previously.<sup>366</sup> In order to improve the molding properties, Nash<sup>364</sup> included in phenol resins 10 per cent of stearin pitch and 3 per cent of sulphur. The residues from the distillation of natural resins and tall oil<sup>365</sup> have been heated with sulphur and the vulcanized products incorporated with phenol-aldehyde binders.<sup>366</sup> A further industrial by-product with which phenol resins can be admixed is the gummy precipitate obtained by acidifying black liquor.<sup>367</sup>

For certain purposes objects with a porous structure are desired. One way in which these may be obtained is by using a filler which can be easily removed. Thus, dissolving out metal wires from a plate of phenol resin forms a series of orifices through which artificial silk may be extruded.<sup>368</sup> Porous bearings have been similarly made by the action of acid on a filler consisting of powdered metal.<sup>369</sup>

(to avoid allowing the water to escape too soon) by the addition of a polymerizing-catalyst.<sup>373</sup> A further porous material consists of a fibrous mass in which there is not enough phenolic binder to completely fill the interstices.<sup>374</sup>

Fuller<sup>375</sup> stated that difficulty is sometimes encountered in determining by inspection whether molded articles have been heated to the right temperature. He suggested that a dye be included which would fade out when the material was hot enough. Malachite green and methyl violet were mentioned, since they are decomposed at about 180° and 220°C. respectively. The presence of 3-5 per cent of water in molding compositions was reported as preventing deformation due to further absorption.<sup>376</sup> Employment of a resin which will absorb not less than 18 per cent of water at 25°C. was also stated to give a laminated sheet with improved bending and splitting strength.<sup>376</sup>

Water-soluble salts of phenol-formaldehyde resins may be dissolved in less than the equivalent amount of alkali and then salted out of solution. When using an equivalent or greater quantity of alkali, the material cannot be salted out. The substances obtained are soluble in water, but when heated or treated with carbon dioxide the solutions are decomposed with partial precipitation of the condensation product. The products were said to find application in the textile industry.<sup>377</sup>

The suggestion has been made that free phenol (1 per cent) be left in molding compositions which were desired to have antiseptic properties.<sup>378</sup> Curley<sup>379</sup> recommended that a thin strip of phenolic resin be included in the frame of a tennis racket. Being tough and impervious to moisture, the insert helps to prevent warping. The difficulty which arises in attaching sheets of phenol-formaldehyde condensation products to metals has already been mentioned. This difference in thermal expansion was put to use by Aylsworth<sup>380</sup> who made molds for cylindrical metallic phonograph records from phenol resin. On warming the matrix, it expanded, freeing the record. Albrecht<sup>381</sup> proposed to fill teeth with a solution containing glycerol, a phenol condensation product and a condensing agent.

When heated to 800-900°C., phenolic resins are carbonized. The resulting material has been used as an absorbent charcoal<sup>382</sup> and in variable-resistance units of telephone transmitters.<sup>383</sup> In the latter case, a fusible condensation product was granulated and melted. The molten particles were allowed to assume a spherical shape and then hardened by slow heating to 270°C. previous to carbonizing. Mixtures of graphite and phenol-furfuraldehyde binders have been molded and then coked to form dynamo brushes.<sup>384</sup> If a small quantity of a rubber-vulcanization accelerator is included, the molded brush is said to be harder and more durable.<sup>385</sup> A similar procedure applies a layer of synthetic resin filled with colloidal charcoal to a ceramic carrier. After carbonization, the product was used in potentiometers.<sup>386</sup>

## Chapter 23

### Aldehyde Resins

Acetaldehyde ( $\text{CH}_3\text{CHO}$ ) is a compound from which various kinds of resins may be made. By self- or auto-condensation, acetaldehyde undergoes two quite different series of reactions, one a carbon-oxygen-carbon, the other, a carbon-carbon union.

By treating acetaldehyde with a small amount of concentrated sulphuric acid, paraldehyde is formed.<sup>1</sup> This substance is readily decomposed by warming with dilute sulphuric acid.

Mild alkaline reagents cause acetaldehyde to undergo a simultaneous intermolecular oxidation-reduction; the  $\alpha$ -hydrogen of one aldehyde reduces the carbonyl in the adjacent molecule with the result that a carbon-carbon bond is formed and the compound so obtained is known variously as  $\beta$ -hydroxybutyraldehyde, acetaldol or simply aldol. The reaction is likewise reversible. More easily, however, a loss of water occurs in acetaldol and crotonic aldehyde results.

Less strenuous acid conditions than used in the formation of paraldehyde also bring about aldolization.

Another type of simultaneous oxidation-reduction can take place, that is, where the aldehyde groupings undergo compensating changes, the so-called Cannizzaro reaction.

This reaction takes place in concentrated alkaline solution.

Consideration will first be given to the various means by which acetaldehyde may be resinified and subsequently to the conditions under which aldolization may take place. Acetaldehyde resins are obtained principally in alkaline solution. There are cases, however, where resinous substances have been formed under acid

<sup>1</sup> Metaldehyde is formed from acetaldehyde and acids at low temperatures, i.e., below  $0^\circ\text{C}$ . Other reagents for the transformation of acetaldehyde to metaldehyde include ammonium bromide, hydrazine hydrochloride, pyridine hydrobromide and perborate, halogenated pyridines, urea hydrochloride, diphenyl thiourea hydrobromide, the hydrohalides of alkylamines and hexamethylenetetramine, tetraethyl ammonium trichloride together with a strong inorganic acid. See British P. 235,867, 1924, to Elektrizitätswerk Lonsa; *Chem. Abs.*, 1926, 20, 917.

conditions and to a slight extent by the action of light and under the influence of atomic hydrogen and enzymes.

#### ALKALINE RESINIFICATION

Acetaldehyde and its derivatives, aldol and crotonaldehyde all undergo resinification in alkaline solution.\* The earliest observations of the resinification of acetaldehyde were made by Liebig<sup>3</sup> and Döbereiner.<sup>4</sup> Döbereiner noted that an alcoholic solution of potassium hydroxide when warmed with acetaldehyde furnished a yellowish or brown resin-like substance. Liebig observed that an aqueous solution of aldehyde, warmed with potassium hydroxide immediately became yellowish and turbid and quickly separated a reddish-brown substance which could be drawn out into long threads. He named the product aldehyde resin and noticed that it had a penetrating odor. According to Weidenbusch,<sup>5</sup> this odor is due to a volatile oil, which is oxidized by air to a resinous body. When dried at room temperature and subsequently over a water bath the resin was reported by Liebig to ignite spontaneously. Weidenbusch did not observe any such ignition.

Barium hydroxide may be used to bring about the condensation and the barium removed as carbonate by carbon dioxide. Filtration and concentration of the aqueous solution leaves a gummy syrup.<sup>6</sup> The resin can also be formed from alcoholic potash if air or some oxidizing agent is present.<sup>7</sup> Ekecrantz<sup>8</sup> prepared acetaldehyde resin as follows:

A mixture of acetaldehyde and alcohol is cooled to  $-20^{\circ}\text{C}.$ , and a 10 per cent alcoholic sodium hydroxide solution is added, the temperature of the mixture being kept below  $10^{\circ}\text{C}.$  The mixture is kept cold for some time, allowed to stand at room temperature for 24 hours and finally heated under a reflux condenser until the aldehydic odor has disappeared. The alcohol is removed by vacuum evaporation at approximately  $30^{\circ}\text{C}.$  A thick reddish-brown residue is obtained which when treated repeatedly with hot 5 per cent caustic soda solution sets to a brittle resin. Purification may be effected by dissolving in glacial acetic acid and precipitating with water. The acidic portion of the aldehyde resin which remains in solution with the caustic soda is obtained by neutralizing the alkali and extracting with ether. A yellowish-brown viscous residue is obtained.

Some elementary analyses of acetaldehyde resin by various early observers are given in Table 29.

TABLE 29.—Elementary Analyses of Acetaldehyde Resins.

	Liebig	Weidenbusch	Ekecrantz*
Carbon.....	73 34	76 40	70.07
Hydrogen.....	7.76	7 97	7.83
Oxygen.....	18.90	21 63	22 1

\* Ekecrantz ascribes the variation in the analytical results to a fluctuating water content.

<sup>2</sup> These three substances are to be treated separately, but it should be borne in mind that many investigators use all three interchangeably and many of the references to acetaldehyde refer or apply to aldol and crotonaldehyde as well.

<sup>3</sup> J. Liebig, *Ann.*, 1835, 14, 140. See L. Gmelin, "Handbook of Chemistry," translated by H. Watts for the Cavendish Society, London, 1866, 17, 456.

<sup>4</sup> J. W. Döbereiner, *Ann.*, 1835, 14, 140. Cf. Gmelin, *loc. cit.*

<sup>5</sup> Weidenbusch, *Ann.*, 1848, 66, 153; L. Gmelin, *loc. cit.*, 1866, 17, 456.

<sup>6</sup> B. Tollens, *Ber.*, 1884, 17, 660.

<sup>7</sup> Alcohol which contains pyridine and aldehyde, when burned in lamps, forms resinous substances, presumably from the condensation of aldehydes formed. See J. Dehnike and W. Kilp, *Z. spiritusind.*, 1926, 49, 280; *Chem. Abs.*, 1927, 21, 167. In Döbereiner's vinegar lamp, alcohol may oxidized to acetic acid in the presence of air. In a deficiency of air, aldehyde is formed; if this is absorbed by caustic potash, a yellow resin is obtained; J. S. Döbereiner, *Schweigg. Jour.*, 1831, 63, 223. See L. Gmelin, *loc. cit.*, 1835, 8, 207; also A. Mittasch and E. Theis, "Von Davy und Döbereiner bis Deacon," Verlag Chemie G.m.b.H., Berlin, 1932, 79.

<sup>8</sup> T. Ekecrantz, *Arkiv för Kemi*, 4, 27, 1; *Chem. Zentr.*, 1912, 2, 1193. See M. Bottler, "Kunstharsen" J. F. Lehmanns Verlag, München, 1919, 42.

By means of the varying solubilities in benzene, Ekecrantz was able to separate aldehyde resin into two components,  $\alpha$  and  $\beta$ ; the  $\alpha$ -resin is soluble in this solvent, the other very much less so. Both resins may be represented by the formula,  $C_{24}H_{36}O_6$  or  $[12(CH_2CHO) - 6H_2O]$ .

Hammarsten<sup>9</sup> allowed aqueous solutions of acetaldehyde to remain for 5-6 days at ordinary temperatures with an equal volume of 10 per cent aqueous potassium hydroxide solution. A red-colored resin was obtained by neutralizing the solution with acid. Further addition of concentrated hydrochloric acid to the filtrate caused the separation of a very pale straw-yellow resin which had a melting point of 120-130°C.; decomposition occurred above 200°C. Analyses revealed a molecular weight of 396-412. Hammarsten was uncertain whether the red resin was formed independently or through the yellow variety. An alkaline solution of the yellow resin did not become turbid when preserved. This suggests that the red resin is formed through a different series of reactions.

Some of the properties of acetaldehyde resin are given by Weidenbusch.<sup>10</sup> He stated that the resin is a bright orange-yellow powder becoming lighter in color on long drying at 100°C. It is soluble in ether and slightly soluble in water. Ekecrantz<sup>11</sup> noted that acetaldehyde resin is soluble in chloroform, alcohol and acetone, only partially soluble in benzene and ether, and insoluble in petroleum ether. At 105°C. the resin sinters and at 130-140°C. melts and intumescs.

The processes described by Liebig, Döbereiner and Ekecrantz remain to this day fundamental for the production of acetaldehyde resin. These resins, as such, have found little place in commerce and many efforts have been made to alter their properties in order that they might be used.

An appreciable quantity of aldehyde resin was obtained by Pauly and Feuerstein<sup>12</sup> by the following procedure: To 1.5 l. of 6 per cent acetaldehyde solution on the water bath at 70°C. were added 40 cc. of 5 per cent caustic potash solution with shaking. As the alkali disappeared, further portions were added, 5 cc. at a time, the total quantity amounting to 65 cc. The mixture was held for 6 hours at 66°C. and a yellowish-red oil subsequently isolated by cooling, neutralizing with acetic acid and salting out with sodium chloride. The product was repeatedly extracted with benzene and the solution in the latter dried with calcium chloride; vacuum distillation yielded 26 g. of resin. In the distillate were detected two unsaturated aldehydes with the formulas,  $C_8H_{12}O_2$  and  $C_{10}H_{14}O_2$ .

According to Herrmann and Deutsch,<sup>13</sup> acetaldehyde resin is acted upon by water to form a muddy material. To eliminate this tendency, 100 parts of acetaldehyde condensation product (produced in the presence of caustic soda) were ground with 200 parts of a 3 per cent aqueous solution of acetic acid. The swollen resin particles were filtered from the resulting suspension and remelted, yielding a body which was no longer acted upon by water. Similar results may be obtained also by dissolving the resinous products in alcohol or acetone and precipitating the dissolved resins from the solution with water.

The degree of hardness of acetaldehyde resins increases, according to Herrmann and Deutsch,<sup>14</sup> with the duration and intensity of treatment with alkali. In a process given by them, 500 parts of acetaldehyde are slowly introduced into a container with 300 parts of 20 per cent sodium hydroxide solution, the latter being cooled and vigorously stirred. The fluid products which are first formed soon become viscous and finally solid upon continued action of the alkali. Depend-

ing on the duration and manner of treatment, the resins are transparent or nearly opaque and may vary from a light yellow to a dark reddish brown. The melting point of the resins may be raised to above 200°C. by continued action of alkali, yielding materials soluble in alcohol, acetone, anhydrous acetic acid, linseed oil and turpentine oil. Solutions of the resins may be used for varnishing and polishing purposes and are reported useful for first-coating and impregnation of wood, cardboard and textiles. The solid resinous mass may be made into shaped articles under the application of heat and pressure. If the resin is dissolved in anhydrous acetic acid and mineral acid added, precipitation with water yields a yellow substance which will not fuse below 300°C.

Acetaldehyde resins are soluble in many organic solvents, but they are not soluble in aqueous solutions of borax and soda which is a characteristic of shellac that permits it to be employed in the manufacture of leather dressings. To make acetaldehyde resins soluble in alkaline solutions, Herrmann and Deutsch<sup>15</sup> subjected them to an oxidation treatment.<sup>16</sup> For instance, to 60 parts of 4 per cent aqueous caustic soda are added 200 parts of acetaldehyde. The temperature is kept for some time between 40-100°C. and the volatile components are distilled off. Further heating is continued at temperatures above 100°C. Ten parts of the resulting resin are dissolved in 100 parts of glacial acetic acid and ozonized oxygen is passed through the solution. When the oxidation has reached the degree desired, water is added which precipitates the resin. The oxidation may also be carried out with the resin in a molten state or when finely divided and suspended in water. Paquin, Voss and Wohlers<sup>17</sup> likewise gave related resins an oxidation treatment. They suspended or dissolved resinous products obtained by condensation of acetaldehyde, crotonaldehyde and aldol in inert media (alcohol or water) and oxidized them with chlorine or potassium chlorate and hydrochloric acid.

Heat treatment of acetaldehyde resins is said to raise the softening point and to increase the hardness, luster, elasticity and utility as varnish resins.<sup>18</sup> The method involves heating the resin at above 100°C. for several hours. Some inorganic metallic compounds<sup>19</sup> are also helpful; by stirring with aluminum hydroxide at 200°C. the softening point may be raised from 110°C. to 150°C.

By the addition of substances containing carboxyl and carbonyl groups,<sup>20</sup> acetaldehyde resins are said to have a better elasticity, solubility in alcohol and a lighter color; appropriate substances include dihydroxystearic acid, ricinoleic acid, dihydroxyabietic acid, mesityl oxide and salicylic acid. One method recommended is as follows: The resinous product obtained on condensing 500 parts of acetaldehyde by 300 parts of 20 per cent caustic soda solution is melted with 30 per cent of its weight of ricinoleic acid and kept in the molten state at 150°C. for a short time. It is rolled out in a milling apparatus to shellac-like sheets. The modifying agents may also be introduced during the resinification process. The resin thus prepared can also be melted with castor oil and further admixed with an alcohol-soluble polymerized vinyl acetate.<sup>21</sup>

Haehnel, U. S. P. 1,643,496, Sept. 27, 1927; *Chem. Abs.*, 1927, 21, 2907. Canadian P. 249,338, 1925; *Chem. Abs.*, 1925, 19, 3381. British P. 201,916, 1923; *J.S.C.I.*, 1925, 44, 45B.

<sup>21</sup> W. O. Herrmann, H. Deutsch and W. Haehnel, U. S. P. 1,985,993, Jan. 1, 1935, to Chemische Forschungsge. m.b.H.

According to Herrmann and Deutsch,<sup>22</sup> acetaldehyde resins mixed with organic substances containing carboxyl groups may be utilized in the manufacture of linoleum. A resin having a softening point of 40-50°C. can be prepared by the partial condensation of acetaldehyde with sodium hydroxide. One hundred parts of such a resin were melted with 85 parts of castor oil and heated for 16 hours at 200°C. whereupon 100 parts of the resulting mix were kneaded thoroughly at 120-130°C. with 30 parts of ground ocher and 15 parts of cork flour. The plastic was calendered in the usual manner on a burlap base. By mixing with various other fillers together with synthetic and natural resins substitutes for cork, horn and ivory may be made.

Resins prepared from acetaldehyde and alkali are said to be improved by heating to 110°C. with polyvinyl acetate or other polyvinyl compounds.<sup>23</sup> Powdered alkali and resin when mixed and heating so arranged as to allow the greatest amount of hydrogen to be split off yielded salts of carboxylic acids.<sup>24</sup>

Acetaldehyde resins may be made soluble in fatty oils by heating them with oil-soluble natural resins (rosin) or by heating at 150-300°C. mixtures of the resins with fatty oils (linseed oil), until a sample remains homogeneous on cooling.<sup>25</sup> The products can be diluted with turpentine. Haehnel and Herrmann<sup>26</sup> rendered acetaldehyde resins soluble in weak alkalies by treatment with strong alkalies in the presence of fatty oils or hydroxy fatty acids derived from them. The treatment may be carried on at ordinary or elevated temperatures. Voss<sup>27</sup> heated the resins prepared by condensation of acetaldehyde with other natural or synthetic resins (rosin or cumarone) until the end product exhibited the solubility properties of the second component. Further hardening of aldehyde resins, after heat treatment, may be effected by esterification with glycerol.<sup>28</sup>

Herrmann, Deutsch and Haehnel<sup>29</sup> produce resins directly from acetylene by causing it to react upon catalyzers in the presence of water and continuing the reaction beyond the intermediate formation of acetaldehyde. An acetaldehyde condensation product is made by Shaw,<sup>30</sup> who reacts the aldehyde at 10-15°C. with 2.2 g. of alkali condensing agent per kg. of finished product (the condensing agent being an aqueous 10 per cent solution) and then treating the resulting mass at 20-45°C. with approximately double the amount of the same condensing agent in a solution of concentration of 20 per cent.

#### ACID RESINIFICATION

Wurtz<sup>31</sup> observed the resinification of acetaldehyde by hydrochloric acid. Herrmann and Deutsch<sup>32</sup> have prepared an aldehyde resin by using 25 per cent sulphuric acid. The temperature is kept at 40°C. for several hours; then raised

to 100°C. The toughness and hardness of the product depends upon the duration of the heating. The resin obtained is said to be suitable for varnishes.

#### VARIOUS OTHER MEANS OF RESINIFICATION

Berthelot and Gaudechon<sup>38</sup> from a study of the photolysis of acetaldehyde vapor found that resinification results only slowly by the action of long ultraviolet rays. Continuing the work, Leighton and Blacet<sup>39</sup> determined that the absorption bands lie between 2730-3400 Å with a maximum at about 3100 Å and produce two reactions, one a decomposition giving principally carbon monoxide and the corresponding hydrocarbon,<sup>40</sup>  $R-CHO \rightarrow RH + CO$ , and the other a polymerization into complex products. The nature of the polymerization products is not stated, presumably they are a mixture of para- and metaldehyde. Other saturated aliphatic aldehydes when exposed to the rays of a quartz mercury lamp exhibited a certain degree of condensation or polymerization to resins.<sup>41</sup> Carbon monoxide was also evolved, a reaction which appears to apply only to this type of aldehyde since no gas was detected on irradiating crotonaldehyde, benzaldehyde and cinnamaldehyde.

Schweizer and Geilinger<sup>37</sup> suspect the existence in yeast of an enzyme aldehydase which brings about transformation of substances of the aldehyde group according to the Cannizzaro reaction. Experiments, in which the masking effect of oxygen was eliminated by means of alkaline pyrogallate, lent support to their view. Bodnar and Bernauer<sup>36</sup> found that pea meal converted acetaldehyde into acetaldol and aldehyde resins.

Slight resinification of acetaldehyde is reported by Urey and Lavin<sup>42</sup> in a study of the reactions of atomic hydrogen. The main reaction, however, is that of paraldehyde formation.

When mercuric nitrate acidified with nitric acid is added either to acetylene or to an alcoholic solution of acetaldehyde, a compound of the formula  $C_2HNO.Hg_2$  is obtained. On warming this mercury derivative with caustic soda or with potassium cyanide solution, a considerable amount of aldehyde resin is formed.<sup>43</sup>

Cyanamide dissolves in acetaldehyde and in 24 hours the resulting solution changes to a resinous body insoluble in water but soluble in alcohol. Ether precipitates the resin from alcohol.<sup>44</sup> Cyanamide reacts violently with chloral forming a sticky resin which hardens in air. This is moderately soluble in alcohol, ether and chloroform but becomes brown on heating and decomposes at 210°C.<sup>45</sup>

Vacuum distillation of the products of the reaction between cinnamic aldehyde and acetaldehyde, in the presence of sodium hydroxide, yields a black tar-like residue. Moreover, the reaction product of acetaldehyde and 5-phenyl-2,4-pentadienal-1, that is, 7-phenyl-2,4,6-heptatrienal-1, when oxidized with ammoniacal silver

<sup>44</sup> Knop, *Ann.*, 1864, 131, 253; "Beilstein's Handbuch der organischen Chemie," 4th Ed., 1921, III, 79.

<sup>45</sup> M. Fileti and R. Schiff, *Ber.*, 1877, 10, 426. G. Heim, (*Bull. soc. chim. Belg.*, 1903, 41, 320; *Chem. Abs.*, 1903, 27, 267) reports that the condensation of cyanoacetic acid in the presence of pyridine results in the production of 50 per cent of tarry material.

oxide to the corresponding acid, becomes partly resinified.<sup>44</sup> According to Rieche,<sup>44</sup> the reaction product of acetaldehyde and hydrogen peroxide is converted by phosphorus pentoxide in ether into a polymeric ethylidene peroxide.

Voss<sup>45</sup> has prepared a water-soluble viscous material by gently heating under reduced pressure the condensate of formaldehyde with acetaldehyde. Polymerized vinyl alcohol-acetaldehyde condensation products are obtained<sup>46</sup> by treating polymerized vinyl alcohols with aliphatic aldehydes such as formaldehyde or acetaldehyde in the presence of acid catalysts. The materials are said to be rubber-like, plastic and elastic or hard and brittle depending on the proportion of aldehyde.

In a study of condensation reactions of acetaldehyde over oxide catalysts at pressures of 1-500 atmospheres of hydrogen, Adkins, Kinsey and Folkers<sup>47</sup> report the production of some tar-like substance. In one experiment in which ethanol and acetaldehyde reacted under high pressure over a zinc chromite catalyst there was about 9 per cent of residue, after distillation of products up to 160°C. at 2 mm. pressure. Manganese chromite catalysts performed in about the same way as the zinc chromite. Copper chromite produced very little tar.

Bodendorf<sup>48</sup> has investigated the reaction of aliphatic aldehydes (1 mol) with a suspension of aluminum chloride (1.2 mols) in benzene saturated with dry hydrogen chloride. Fifty per cent yields of the corresponding diaryl paraffins were obtained. The by-products were alkylbenzenes and resinous materials.

#### USES OF ACETALDEHYDE RESINS

In addition to the uses for these resins already indicated, Osborn<sup>49</sup> suggests their use as dental impression compositions. Further uses are as agglutinants in the manufacture of micanite and other electrical insulating materials<sup>50</sup> and for photographic filters. A bright yellow light filter may be formed from cellulose ethyl ether and acetaldehyde resin.<sup>51</sup> Bradshaw<sup>52</sup> made a casein glue by the addition of polymerized acetaldehyde to a dry glue base containing casein, hydrated lime and alkali salts.

#### ACETALS

Acetal, when kept out of contact with air, does not react with alkali at ordinary or at higher temperatures.<sup>53</sup> In the presence of air, however, or in alcoholic potash solution, acetal readily darkens with the formation of a dark resin.<sup>54</sup> Acetylene, which functions as anhydrous acetaldehyde, may be hydrated to acetaldehyde by means of a catalyst consisting of mercuric sulphate and sulphuric acid. Similarly, alcoholation yields acetals, i.e., diethyl acetal is formed in the case of ethyl alcohol. On continued passage of acetylene, however, crotonaldehyde appears as an intermediary and the final product is a black resin. Fusel oil, when treated in the same

manner, quickly thickens into a jelly-like mass which hardens into a solid body resembling hard rubber.<sup>55</sup>

Methylal is produced in 97 per cent of the calculated yield by reacting 2 mols of methanol with 1 mol of trioxymethylene in the presence of ferric chloride. The latter is the most effective of the many catalysts examined. All the catalytically active salts examined were capable of forming alcoholates. The catalysts did not induce polymerization of the aldehyde during the usual time involved in the acetal reaction.<sup>56</sup>

#### MANUFACTURE OF ACETALDEHYDE

Much difficulty is experienced in the synthesis of acetaldehyde from acetylene<sup>57</sup> inasmuch as the reaction is carried out in acid solution which is an appropriate medium for the formation of aldehyde resins.

Formation of resinous matter when working at temperatures of 70-90°C. is avoided by using as catalyst for the conversion, an aqueous solution of an alkali hydrogen sulphate, containing a mercury compound and a compound of a metal of group I or VIII.<sup>58</sup>

In another method, resinification is avoided by continuously circulating the liquid between the reaction chamber and another chamber where the aldehyde formed is isolated by vacuum distillation.<sup>59</sup>

Continuous and regular formation of acetaldehyde was effected by Ledru and Bachmann<sup>60</sup> using a mercury salt as a catalyst in the oxidation of acetylene. A mixture of acetylene and 2-20 per cent of oxygen was allowed to stream through a stirring apparatus containing 4.3 kg. of 100 per cent sulphuric acid, 1 kg. of ferrous sulphate, 0.300 kg. of mercury, 0.150 kg. of crystalline copper sulphate and 16 l. of water. Acetic acid is also produced.

Snow and Keyes<sup>61</sup> investigated the influence of about 150 substances upon the partial oxidation of liquid ethyl alcohol both at atmospheric pressure (72°C.) and at 170 pounds per square inch (100°C.). Compared with vapor-phase oxidation, better temperature control is possible in the liquid phase owing to the high specific heat. Alcohol containing a catalyst in suspension or solution was placed above the porous plate of a Schott filter funnel kept at 70-75°C. by steam heat, and oxygen was forced through the plate. No acetic acid was formed at atmos-

TABLE 30.—*List of Substances Having Catalytic Activity.*

Group of the Periodic Table	Substances Which Catalyze the Oxidation of Alcohol to Aldehyde.
I	Copper and copper-zinc couple.
II	Soluble salts of mercury, zinc and cadmium.
III	Soluble salts of aluminum and metallic boron, aluminum and indium.
IV	Soluble salts of lead, tin and titanium, also the corresponding metals.
V	Vanadium pentoxide and acetate, phosphotungstic and phosphomolybdic acids, also phosphorus pentoxide.
VI	Chromous acetate, potassium dichromate, chrome alum and selenious acid.
VII	Manganese acetate, sulphate, oxide and metallic manganese.
VIII	Soluble salts of iron, cobalt and nickel, also metallic palladium, iron, cobalt and nickel.

pheric pressure and acetaldehyde represented the limit of oxidation except in one instance. Cerium oxide in the presence of alkali led to formation of acetic acid, formic acid, acetaldehyde resin and carbon dioxide. A list of some of the other substances which exhibited catalytic activity is given in Table 30 (on page 496). Rare earths were ineffective but hopcalite (a combination of manganese, copper, silver and cobalt) was quite active. Good results were obtained with hopcalite and cerous hydroxide in sodium carbonate solution.

#### ACETALDOL AND CROTONALDEHYDE

One of the chief drawbacks in aldolization, according to Kyriakides,<sup>62</sup> is the fact that both aldehydes and aldols<sup>63</sup> are sensitive to alkalis so that there is more or less resinification during the reaction.<sup>64</sup> The older investigators circumvented the difficulty by using very mild alkaline reagents to effect the condensation; the later methods are to use strong alkali in the presence of organic solvents. Through this means the aldol is continually extracted from the sphere of further action of the alkali. Grignard and Rief<sup>65</sup> used sodium sulphite and large amounts of ether. Hibbert<sup>66</sup> dissolved acetaldehyde in gasoline and treated the solution, after cooling to  $-10^{\circ}\text{C}.$ , with sodium or potassium hydroxide. The end-point of the condensation may be judged by the light yellow color in the aldol liquid. This color is a sign of the formation of higher condensation products. For maximum yield of the aldol, the liquid should be colorless at the end of the reaction.

Grünstein<sup>67</sup> effected aldolization without using a solvent. Acetic acid in the aldehyde was first neutralized with sodium hydroxide and an alkaline catalyst was introduced with cooling. A small amount of water appeared to be essential. To prevent the condensation from going too far, acid was added and the products distilled *in vacuo*.

To produce acetaldol, Matheson<sup>68</sup> added 1.3 cc. of a 10 per cent caustic soda solution slowly with stirring and cooling to 200 g. of acetaldehyde which had been previously cooled to about  $-25^{\circ}\text{C}.$  The initial reaction was very vigorous and the material had to be kept below  $10-20^{\circ}\text{C}.$  in order to prevent resinification. After 30 minutes, the material was a thick colorless product from which the remaining aldehyde and water were distilled. The aldol could be distilled *in vacuo*. Other investigators aldolize aqueous acetaldehyde in the presence of alkali, keeping the temperature at  $15^{\circ}\text{C}.$ <sup>69</sup> or below, or pass the acetaldehyde and condensing agent through reaction chambers provided with cooling coils.<sup>70</sup>

Herrly<sup>71</sup> stated that the reaction is more easily controlled when the alkali concentration is low and the temperature is high. According to his directions, the acidity of the acetaldehyde, which is due to organic acid impurities, is first

<sup>62</sup> L. P. Kyriakides, *J.A.C.S.*, 1914, 36, 352.

<sup>63</sup> Aldols form a complex with "dimedon" (dimethyldihydro-resorcinol) which can be differentiated from the analogous acetaldehyde complex by its insolubility in light petroleum. See R. Fricke, *Z. Physiol. Chem.*, 1921, 116, 129; *J.S.C.I.*, 1922, 41, 268A.

<sup>64</sup> M. C. Reed (U. S. P. 1,763,326, June 10, 1930, to B. F. Goodrich Co.; *Chem. Abs.*, 1930, 24, 3799) has found that the addition of a small amount of secondary aromatic amine (phenyl- $\beta$ -naphthyl amine) effects the stabilisation of butyraldehyde. Resinification may be avoided in the preparation of cyanohydrins of aliphatic or aromatic aldehydes or ketones, or of alkylene oxides, when the reaction takes place in the presence of an organic base of a concentration of 0.1-1.0 per cent of the hydrogen cyanide. <sup>71</sup> C. J. Herrly, U. S. P. 1,598,532, Aug. 31, 1926, to Carbide & Carbon Chemicals Corp.; *Chem. Abs.*, 1926, 20, 3461.

By heating dialdan with aqueous ammonia under pressure at 100°C., a resinous body is obtained which is crystallizable and which possesses the formula,  $C_{10}H_{20}N_2O_4$ . It is soluble in ether, alcohol and water. Its aqueous solution is alkaline, however, and long standing in water causes an amorphous body to settle out.<sup>64</sup>

Hammersten<sup>65</sup> observed that aldol does not disappear during resin formation even at higher temperatures or at longer reaction times. The first condensation product is changed in part to higher aldols, of which 3,5,7-trihydroxy-1-octanal,

has been isolated. In no experiment, under the conditions reported, was less than 40 per cent of aldol obtained from 0.5 *N* acetaldehyde solution. This may be taken to mean that the higher aldols do not form aldehyde resins. With higher concentrations of alkali the Cannizzaro conversion was more pronounced than with lower concentrations; this was the case with potassium hydroxide. With barium hydroxide, the concentration was not so important. Lead hydroxide had a specific action since noticeable aldol formation took place, but neither the Cannizzaro effect nor resin formation occurred.

An instructive condensation in this connection has been worked out by Zeisel and Neuwirth<sup>66</sup> for the autocondensation of acetaldehyde in the presence of sodium acetate. The action is shown as follows:

Both  $\alpha$ -vinyl crotonaldehyde (2-vinyl-2-butenal-1) and sorbaldehyde (2,4-hexadienal-1) were isolated and their boiling points at 24 mm. are 55-60°C. and 75-80°C., respectively. Both substances resinify easily.

Aldol can be polymerized in the presence of either calcium or magnesium oxide without the formation of insoluble resins if the temperature is maintained under 70°.<sup>67</sup> Resins are obtained, however, when the mixture remains alkaline to phenolphthalein during the reaction. Under these conditions a compound of approximately twelve carbon atoms to the molecule is formed.<sup>68</sup>

Treatment of acetal with cold acetic anhydride in presence of pyridine was found by Bergmann and Kann<sup>69</sup> to lead to formation of acetylcycloaldol or paral-dol diacetate (b.p. 156-158°C. at 12 mm.),

It yields a colorless viscous oxime boiling at 120-122°C. at 12 mm. In the same way, aldol-dimethylacetal yields acetylaldoldimethylacetal (b.p. 84-86°C. at 13 mm.),

<sup>69</sup> M. Bergmann and E. Kann, *Ann.*, 1924, 436, 278; *Chem. Abs.*, 1924, 18, 3358.

This substance is hydrolyzed to 3-acetoxybutanol, which forms the same oxime as the above acetylcycloaldol. The tendency to polymerization of the aldolcycloacetates was ascribed to the unsaturated affinity of the bridge oxygen and is more pronounced the shorter the space between the two carbon atoms thereby linked.

The action of hydrochloric acid on acetaldol produced resinification as well. Glassy solids have been prepared in this manner.<sup>90</sup> In studying methods for preparing 1,2-dimethylcyclopropanes, Baudrenghien<sup>91</sup> obtained solely resinous products on treating aldol with hydrochloric acid.

#### CROTONALDEHYDE

Crotonaldehyde, which, as has been previously indicated, is a dehydration product of acetaldol, is formed when the aldol is acidified with a weak mineral acid.<sup>92</sup> It can also be produced by means of catalysts. Thus, aldol may be converted to crotonaldehyde in alkaline solution by heating with salts of organic acids.<sup>93</sup> Herrly<sup>94</sup> introduced aldol into a heated zone in a current of nitrogen, steam or other inert gaseous medium in order to prepare crotonaldehyde. Acetaldehyde vapor may be passed over catalysts such as charcoal coated with titanium oxide or masses of aluminum hydroxide to produce crotonaldehyde.<sup>95</sup> Brus<sup>96</sup> produced crotonaldehyde from alcohol by the action of anhydrous zinc sulphate, the alcohol being dehydrogenated to the aldehyde, condensed to aldol and dehydrated to crotonaldehyde.<sup>97</sup>

Crotonaldehyde forms a resin in both alkali and acid.<sup>98</sup> When dissolved in ether and treated with ethereal hydrogen bromide at  $-5^{\circ}\text{C}.$ , crotonaldehyde forms highly polymerized products.<sup>99</sup> Treatment of this aldehyde with sodium amalgam also causes resinification.<sup>100</sup> A resinous product is produced from crotonaldehyde and an aromatic amine.<sup>101</sup> For example, to 56 parts by weight of crotonaldehyde, 60 parts by weight of aniline are gradually added with stirring. The temperature during the process is not allowed to exceed  $50^{\circ}\text{C}.$  When all the aniline has been added, the reaction mass is further stirred for 3 hours at this temperature whereupon it is allowed to stand over night. The residue obtained by vacuum distillation of the volatile constituents is a brittle resin.

On passing oxygen through crotonaldehyde at  $70^{\circ}\text{C}.$  for several days, crotonic acid may be obtained together with acetic acid and a resinous condensation product.<sup>102</sup> Resin formation as a result of oxidation of crotonaldehyde with gaseous oxygen has also been recorded by Young<sup>103</sup> who agitated the reaction mixture in a closed system at a temperature reaching  $50-90^{\circ}\text{C}.$ , for 10-15 minutes. By maintaining the temperature below  $30^{\circ}\text{C}.$ , resin formation was largely avoided.

Tricrotonylidenetetramine,  $C_{12}H_{24}N_4$ ,<sup>104</sup> is made by heating crotonaldehyde or acetaldo with ammonia. On heating the amine with hydrochloric acid, a resin is formed together with ammonium chloride.<sup>105</sup> Crotonaldehyde phenylhydrazine is decomposed by glacial acetic acid into a resin and acetylphenylhydrazine.<sup>106</sup> The reaction of crotonaldehyde with sodamide in ether produces resinous material.<sup>107</sup>

#### ACROLEIN

Acrolein, or acraldehyde,  $H_2C=CH-CHO$ , is usually made from glycerol.<sup>108</sup> Like many aldehydes it forms a number of polymerization products, but little is known concerning their structure. The polymers are ordinarily white and amorphous, although a powder and a gel have been prepared.

Acrolein changes easily to a white amorphous product, known as "disacryl," which is insoluble in water, acids, alkalis or alcohol. The effect of light, oxygen and inhibitors on the transformation of acrolein to disacryl has been studied by Moureu, Dufraisse and associates<sup>109</sup> in connection with their work on anti-oxygenes and negative catalysis. Acrolein is stable in the absence of oxygen and light. Upon exposure to light, however, disacryl is produced immediately, the change being detectable by cloudiness. The speed of the condensation can be increased about 500,000 times by bright sunlight; the variation in rate is not proportional to that of the illumination. Of the portions of the visible spectrum, indigo produced the most rapid condensation to disacryl; violet somewhat less. Disacryl is also produced when acrolein is exposed to oxygen even in complete darkness: very small amounts of oxygen are said to be effective (1:1,000,000). According to Moureu and Dufraisse the catalysis is due to a compound formed by acrolein with oxygen. When light and oxygen act together their action is not mutually complementary but rather inhibitory. Many phenols such as quinol and pyrogallol prevent the condensation, shielding acrolein from the effect of both light and oxygen.

McLeod<sup>110</sup> found that alkaline substances greatly accelerated the polymerization of acrolein. One of his experiments is as follows: to 23.5 g. of acrolein dissolved in 184 cc. of cold water was added 0.1 g. of potassium carbonate in 2 g. of water. An immediate turbidity occurred and a voluminous white substance soon separated with marked evolution of heat. After 18 hours, the odor of acrolein had disappeared; further addition of 0.1 g. of potassium carbonate was made and after 24 hours standing the products of polymerization were found to weigh 22.5 g. The polymer softened at 83°C. and decomposed with gas evolution at 94-95°C. A strong odor of acrolein was observed on warming with dilute acids or alkalis or on heating alone to 100°C. Like disacryl, McLeod's polymer is insoluble in water and glacial acetic acid; it is also insoluble in carbon bisulphide, benzene, ether and petroleum ether, but dissolves in warm 95 per cent alcohol. The polymer is insoluble in aqueous sodium carbonate; in 10 per cent aqueous sodium hydroxide a red-colored solution results. Digestion of this solution for a short time at 100°C. and subsequent neutralization with hydrochloric acid precipitates an amorphous substance of a very high melting point, the weight of which is about one-half of that of the polymer in solution.

<sup>104</sup> M. Delepine, *Compt. rend.*, 1907, 144, 853; *Chem. Abs.*, 1907, 1, 2087.

<sup>110</sup> A. F. McLeod, *Am. Chem. J.*, 1907, 37, 20; *Chem. Abs.*, 1907, 1, 717.

Nef<sup>111</sup> obtained from acrolein in the presence of barium hydrate a polymer which softened at 115°C. and decomposed at 128-130°C. When dissolved in 10 per cent sodium hydroxide solution and heated, Nef's polymer gave rise to the same end product as that obtained by McLeod. None of the products obtained by McLeod or by Nef could be crystallized.

Moureu and Dufraisse<sup>112</sup> further investigated the resinification of acrolein in the presence of aqueous alkali and other catalytic agents. Instead of allowing the reactants to stand for a time (McLeod's procedure) they immediately filtered, washed and dried *in vacuo* the voluminous precipitate which is formed when a resinifying agent is added to an aqueous solution of acrolein. They obtained a white powder which is insoluble in water and hydrocarbons, but very soluble in the cold in many organic solvents, particularly alcohols, ketones and acids. The products formed by this method are said to have better solubility than those of McLeod. The resin in powdered form agglomerates to a viscous mass at temperatures between 80-110°C.

Other reagents which bring about the polymerization of acrolein to resin are potash, soda, lime, lead hydroxide, ammonia, methylamine, aniline, ferric chloride, lead acetate and hexamethylenetetramine-triphenol.<sup>113</sup>

Moureu and Dufraisse<sup>114</sup> state that pure acrolein, which at ordinary temperatures is a mobile liquid, changes under the influence of certain alkaline reagents into a viscous liquid which slowly passes into a solid resinous substance. This process, which has been referred to as a gelation, has been studied by Tampier and Gailliot,<sup>115</sup> who find that a large number of substances, but especially free alkalies and carbonates, catalyze the reaction. During the gelation the volume decreases about 25 per cent and heat is evolved. The change in density takes place rapidly during the first 10-15 days and continues slowly for months. It was also found that the electrical resistance of the gel increases linearly with its age.

No one, so far as is known, has investigated the structural relations<sup>116</sup> between disacryl, the polymer obtained in aqueous alkaline solution and the gelation product. Moureu and Dufraisse<sup>117</sup> state that disacryl formation and the conversion of pure liquid acrolein are two distinct reactions and take place concurrently. They also state that while oxygen has a catalytic effect on the formation of disacryl it has no effect at all on the other reaction.

An examination of the regular series of lines resembling furrows produced on the cut surface of an acrolein gel indicated that the greater part of the incident light is diffracted. It is believed that these furrows are present in the gel before fracture and consist of fine fissures (less than 0.5  $\mu$  long).<sup>118</sup> In common with other amorphous substances, acrolein resin exhibits the phenomenon of "amorphous expansion." This is due to an increase in the coefficient of expansion and not to the change of dimensions at the transition point; the latter phenomenon is typical of allotropic transformations.<sup>119</sup>

## ACRYLIDENE GLYCEROL

Hibbert and Whelen<sup>120</sup> have brought evidence to show that the non-polymerizable product of reaction between glycerol and acrolein without a catalyst under low pressure (repetition of Nef's work)<sup>121</sup> possesses the following structure:

A second isomer is possibly formed as required by Michael's partition principle but no doubt undergoes spontaneous polymerization and remains in the viscous undistillable residue which is always left in large proportion. In the monomeric form it would possess the structure:

The methyl ether of 1,2-acrylidene-glycerol is described as a mobile liquid, monomolecular in the freshly prepared condition but changing after several months into a viscous product (probably a dimer). Polymerization with subsequent ring closure is mentioned as one possible cause of the change. Distillation of 1,2-acrylidene-glycerol results in the formation of a large amount of unidentifiable caramel-like, dark brown residue. Attempts to polymerize 1,2-dihydroxypropylidene-glycerol

were unsuccessful. Hibbert and Whelen subjected the compound for several weeks to a temperature of 110°C. in the presence of various non-acid catalysts. No polymerization was observed. Negative results also followed prolonged heating in the absence of a catalyst or exposure to sunlight in a quartz glass tube. Nor was any tendency to polymerization observed in the case of the methyl ether. These facts are interesting on account of the relationship of the substances to cellulose and other polysaccharides.

Aqueous or alcoholic potash or silver oxide react with acrolein to form a yellow amorphous substance insoluble in water and soluble in alkalis, alcohol and ether.<sup>122</sup> A brown resin is formed when acrolein is heated for several days with 2-4 volumes of water at 100°C.<sup>123</sup> The product is somewhat soluble in water and easily soluble in alcohol or ether. Aeraldehyde reacts with ammonia to form a red amorphous substance easily soluble in water and acids.<sup>124</sup> By the

action of water, lead oxide and silver carbonate on the cyclopropene dibromide, acrolein and polymers are formed. With water, above 150°C. a hard dark resin containing oxygen resulted.<sup>125</sup>

Auwers and Kreuder<sup>126</sup> mixed phenylhydrazine and acrolein and obtained a high proportion of resinous bodies. Tiglic aldehyde ( $\alpha,\beta$ -dimethylacetaldehyde) and phenylhydrazine when heated in the presence of acetic acid also yielded a resin. Lankelma and Sharnoff,<sup>127</sup> in a study of the reactions of 2-amino-4-chlorothiophenol with aldehydes, obtained only resinous products with unsaturated aldehydes.

Complete transformation, that is, in 100 per cent yield to a resin suitable as an ingredient of varnishes, is obtained by Moureu and Dufraisse<sup>128</sup> by condensing phenol and anhydrous acrolein in the presence of a very small proportion of an alkali catalyst. On bringing into contact, for example, 10 parts of commercial phenol and 90 parts of anhydrous acrolein in the presence of 1 part caustic soda, spontaneous resinification takes place at ordinary temperature, but is accelerated by heating at a temperature not exceeding 100°C. The reaction may also be carried out in a solvent and the proportion of acrolein can be varied as desired from 90 per cent (as in the above example) down to 20 per cent. Hydroxyphenylacroleins readily resinify in the presence of alkali hydroxide.<sup>129</sup> The resin-forming tendency can be suppressed by transformation of the hydroxyl group into the methoxy-methoxy-residue,  $\text{CH}_3\text{—O—CH}_2\text{—O—}$ .

Ushakov and Obriadina<sup>130</sup> used either mercuric or copper sulphate as catalysts in the formation of aldehydic resins from glycerol.<sup>131</sup> These resins, when used in conjunction with phenol resins, are said to impart elastic properties to the latter.

Polymerization of glycerol or other higher polyhydric alcohols with aqueous mercuric chloride or sulphate, cuprous chloride or ferric chloride leads to the formation of substances which may be used as explosion-proof lubricants for oxygen cylinders.<sup>132</sup>

### USES OF ACROLEIN RESINS

The polymers made by Moureu and Dufraisse<sup>133</sup> when dissolved in organic solvents can be used as varnishes. Acrolein resins possess good insulating properties. One sample gave volume resistance (23°C.)  $6 \times 10^{15} \sim 10^{16}$  ohms cm., surface resistance (humidity 90 per cent)  $10^{15} \sim 10^6$  ohms, dielectric constant  $4.06 \sim 4.32$ .<sup>134</sup> Work on the insulating power of acrolein gels has also been conducted by Tampier and Gailliot.<sup>135</sup> The so-called "Orca" resins of industry are formed from glycerol and are probably acrolein condensation products.<sup>136</sup>

Acrolein derivatives which act as accelerators of rubber vulcanization and as

Acrolein resins are said to have certain advantages over phenol-formaldehyde resins when they are made by reacting phenol and glycerol in the presence of a catalyst. The glycerol cannot be replaced by glycol. See G. S. Petrov and Y. A. Shmidt, *Plasticheskie Massy*, 1931 (1-2), 27; *Chem. Abs.*, 1932, 26, 3390.

anti-agers for rubber goods are obtained by condensation with aromatic bases. In one example, 39 parts of  $\alpha$ -ethyl- $\beta$ -propylacrolein dissolved in 60 volumes of benzene are heated with 21 parts of aniline in 25 volumes of benzene for 3-4 hours on the water bath under reflux. Benzene and water of reaction are driven off and the residue heated for several hours at 130°C. under 12 mm. The liquid residue is difficultly soluble in water and dilute acetic acid but easily soluble in organic solvents. The following is regarded as the probable chemical constitution:<sup>187</sup>

#### SATURATED ALIPHATIC ALDEHYDES

A very interesting study of polymerization of aldehydes under high pressures was made by Conant and Peterson<sup>188</sup> who prepared the polymers of normal and isobutyraldehyde, n-valeric aldehyde and n-heptaldehyde. From their experiments, it was concluded that a very small trace of a peroxide is essential for the change. A series of chain reactions in the liquid initiated from time to time by spontaneous decomposition of the peroxide are held to be responsible for polymerization. High pressure accelerates the reaction by arranging the molecules of aldehyde into a more compact mass in which longer reaction chains are developed on decomposition of a single molecule of peroxide. With increasing pressure and consequent diminution in the volume of liquid, the molecules begin to assume a definite orientation which is regarded as closely resembling that of the polymer itself. The fact that the polymer is more dense than the original material supports this contention. The formation of long reaction chains is probably encouraged by the spontaneous decomposition of peroxide molecules, each molecule in turn becoming activated by the decomposition energy of the peroxide and consequently joining up with an adjacent molecule. Pressure polymerization is thus visualized as a chain reaction in which a chain-like transmission of energy occurs and the increased rate of polymerization at high temperature is regarded as due to the increased frequency of peroxide decomposition and consequently the formation of more numerous reaction chains.

Freshly distilled acetaldehyde containing 5 per cent benzoyl peroxide polymerized to a hard solid under the usual conditions (see below) but failed to polymerize after heating out of contact with air for 115 hours. The presence of other liquids also diminished the rate of polymerization owing presumably to the hindrance which prevents the production of long reaction chains. On adding, for example, 10 per cent by volume of absolute ethyl alcohol to butyraldehyde which had absorbed considerable oxygen, a paste instead of a solid was obtained after 24 hours at 12,000 atmospheres; 15 per cent of alcohol completely prevented polymerization for 24 hours at 12,000 atmospheres while 28 per cent of n-butyric acid produced a similar effect.

As prepared at 12,000 atmospheres, the aldehyde polymers are hard transparent solids but at 4000-6000 atmospheres using benzoyl peroxide as the catalyst, the polymer is white. Completely polymerized butyraldehyde is insoluble in all common solvents and swells like rubber in benzene and toluene without dissolving. It does not possess any melting point, increase in temperature merely accelerating decomposition to n-butyraldehyde. Complete depolymerization is strongly

catalyzed by aqueous acids or alkalies which bring about the change at atmospheric pressure in a few minutes at 25°C.

#### ALDEHYDE RESINS FROM PETROLEUM

James<sup>139</sup> describes a method for the production of resins by condensation of aldehyde-acids obtained by the partial oxidation of petroleum hydrocarbons. The aldehyde-acids were prepared by partial combustion of Pennsylvania gas oil and contained some unconverted hydrocarbons. Potash soaps were formed from the aldehyde fatty acids and separated from the reaction mixture. The soaps were then treated cold with a slight excess of 4 per cent hydrochloric acid and resinification took place immediately. The resinified acids were washed with water and dried. The color of the resin-acid mixture was light brown; it was brittle at room temperature, softened at 72°C. and melted at 100-120°C. The mixture of resin acids dissolved readily in benzene. The solvent evaporated rapidly, leaving a dark brown varnish coating which was tough and hard and possessed a gloss. Various other resins were obtained by change of conditions such as acid concentration and heat treatment and the use of a different crude oil. Another means of treatment of the partially oxidized hydrocarbons is with liquid sulphur dioxide to remove the unsaturated hydrocarbons. Subsequent boiling with 40 per cent aqueous formaldehyde yields a resin which may be used as a shellac substitute.<sup>140</sup>

#### HALOGENATED ALDEHYDES

In the preparation of 1,2-ethoxy-5-methoxy-3-pentyne by the action of chloroacetaldehyde on a mixture of ethyl magnesium bromide and methyl propargyl ether, the polymerization products of the aldehyde were resinified by potassium hydroxide.<sup>141</sup>
